JENA^ER GLAS

The Water Bi-Distiller according to Zellner will produce 4 litres per hour of sterile bi-distillate of the highest purity, which will be gas and pyrogen free, as well as devoid of residue. Its electrical conductivity is better than 1. 10—6 Siemens. The pH value of 6.9 signifies its freedom from gases, particularly carbonic acid. The high degree of purity is attained by reason of the fact that in the second distillation the water boils in a vacuum. Special arrangements enable the vacuum stage to be kept pyrogen free.

JENA^ER GLASWERK SCHOTT & GEN. MAINZ
(Western Germany)

AUTOMATION IN THE POST OFFICE: TECHNOLOGY AND HUMANISM

THE changes in the telephone service of Britain announced by the Postmaster-General in the House of Commons on November 13 and outlined more fully in a White Paper* published that afternoon have more than usual scientific and technical interest. Essentially they represent a dividend to the nation from an investment in technology. They provide also a striking example of the contribution which automation can bring to the improvement of conditions of everyday life and the way in which a service, hitherto expensive, comparatively restricted and sometimes slow, can be made cheap, almost universal and generally rapid. Perhaps even more important, they provide a noteworthy example of the way in which technical change such as automation should be handled; not merely its effect on the worker is discussed but also its dependence for full effect on his co-operation and understanding (see also p. 92 of this issue).

The White Paper explains that the Post Office is taking two big steps towards full telephone automation, and is pressing on quickly with a system in which all numbers are obtained automatically and charges for calls are recorded mechanically, thus giving better service at lower cost. The first step is to remove the system of charges designed for manual operation, which has hindered progress ever since the first automatic exchange was opened in 1912. Accordingly, from January 1, 1958, the present 6,000 exchanges, each with its own list of charges, will be reduced to about 600 charging units which will be called groups, and all exchanges in a group will have the same list of charges. In consequence, any subscriber will be able to call any other subscriber within his own group or an adjoining group (with few exceptions) for 3*d*., and existing equipment will be fully used for the first time. The 150 million calls a year now handled by operators will be dialled direct by subscribers, with very little additional equipment, and telephone costs will be cut by £2 million a year. Most trunk calls will also be cheaper under the new system; though about 3 per cent will be slightly dearer.

This step paves the way for the second step of full automation which is to follow later, commencing with the exchange at Bristol. Local, toll and trunk exchanges will be merged into one fully integrated automatic unit so that ultimately subscribers will be able to dial all calls. Charges will be recorded automatically on the subscriber's meter, eliminating all possibility of human error, and the minimum three-minute charge will be abolished. Ultimate savings in operating and accounting of £15 million a year are visualized, and by the end of 1958 it is expected that subscribers in Bristol will be able to dial about half the subscribers in Britain. Forty other towns will be similarly equipped by the end of 1960, and by 1970 three-quarters of all trunk calls in Britain will be dialled by subscribers.

The 'brain' of the new system is a robot telephone operator devised by Post Office research engineers and known as Group Routing and Charging Equipment, or 'Grace'. It will interpret the numbers dialled by subscribers, and route calls in the required direction, operate switches at intermediate telephone exchanges until the required exchange is reached, and then dial the number on that exchange. Some operators will still be required to provide such specialized services as personal calls, reverse charge calls, etc.; but the number of telephone operators will be greatly reduced during the next ten years and the automatic accounting already noted will also eliminate the work of 1,500 clerks.

The White Paper emphasizes that the biggest problems of this automation of the telephone system are not in the technical field; the human problems are much greater. Men and women are displaced, less staff is required and prospects of a career are jeopardized. The Post Office is well aware of the anxiety and hardship that could be caused in this way, and intends that this development shall be undertaken with the good-will of the staff. Full regard will be paid to the interests of those who have given long service, and to such added responsibilities as the staff may carry in future. These problems will be tackled by the Post Office and the trades unions together, and the Post Office trades unions have already declared their willingness to co-operate and to serve on working parties set up to consider the introduction of telephone automation and its problems.

These two steps together constitute the most sweeping and radical reform of the telephone service of Britain since the Post Office took over in 1912. Technically, they represent an advance of which Britain has a right to be proud, and a demonstration of how closely scientific and technical advance touches the everyday life of the community. They show that technical advance can—as it should—be shared with the community that pays for it, and perhaps the deepest interest of the White Paper even to the scientist and technologist is in the evidence it affords of the care which the Post Office has given to the social implications of automation. Lord Halsbury's arguments are seen here to be accepted and applied, and are in accord with the conclusions of the recent studies of PEP in this field.

Here, however, a remark which the Postmaster-General made should be noted. He pointed out that the development had been brought about not by new machinery but by the better use of existing machinery. Mr. Marples claimed categorically that the benefits now offered to the nation have been made possible by the removal of administrative restrictive practices from the machinery or equipment already available and not being fully or efficiently used.

---

* Full Automation of the Telephone System. Pp. 14. (Cmnd. 303.) (London: H.M. Stationery Office, 1957.) 9*d*. net.

Mr. Marples may have been using the term 'restrictive' in the sense of 'obsolete', but the point is important. If Britain is to enjoy the full benefits which automation and other major technological developments like nuclear power offer, such developments must be operated under the appropriate conditions. The proper return on the vast investment involved will not be secured unless the equipment is operated at full load; and this is equally the case for investment in roads, railways and coal mines and also nuclear power.

It is true that, as the White Paper makes clear, in these developments in telecommunications there is little danger that the replacement of the drudgery of many by the skill of a relatively few technicians will involve large or sudden dismissals of staff; but the Post Office is taking no chances that normal wastage will not suffice to meet the situation and is adopting appropriate measures to deal with the human problems. Nor is it not simply in this respect that the whole attitude revealed in the White Paper is of outstanding interest. It was a main argument in the report by Prof. C. F. Carter and Prof. B. R. Williams on "Industry and Technical Progress" that lack of vision and enterprise and obsolete or restrictive practices both on the part of management and of trades unions in important sections of industry in Britain were preventing the adoption and exploitation of inventions and new discoveries. We have here a first-class illustration of the dividends in saving of labour and reduction of costs which a forward-looking attitude can pay in both social and commercial life, and also of the way in which problems of technological development should be approached.

Tribute has rightly been paid to the research workers whose achievements have made these advances possible. It is no less fitting that tribute should be paid to the vision and enterprise of the management that has broken through the practices and methods that have hitherto prevented Britain from enjoying the advantages those achievements offered; and also to the courage and responsibility of the trades unions concerned as well as of the management in tackling the human problems of adjustment with sympathy and openmindedness. The example which the Post Office is setting of the way in which to face the human problems of technological advance could prove one of the most important benefits the nation will reap from this striking development; this must be as significant as its demonstration that full use of technological advance can reduce prices and costs for the benefit of the whole economy. It could also assist to establish that confidence in the scientist and technologist and dispel the suggestion of mystery with which they are surrounded, thus making a further contribution to the effective use both of science and technology.

THE SEROLOGICAL APPROACH TO THE STUDY OF PLANT VIRUSES

Plant Virus Serology

By R. E. F. Matthews. Pp. xii+128+6 plates. (Cambridge: At the University Press, 1957.) 27*s.* 6*d.* net.

THE fact that plants do not apparently give rise to antibodies is liable to cause some confusion on the question as to how serology can have an application in the study of plant viruses. However, in 1928, Helen Purdy Beale demonstrated that the virus of tobacco mosaic was a good antigen; in other words, that the blood of a suitable animal, usually the rabbit, contains antibodies which react specifically in an observable way to the virus antigen when injected into it. This discovery provided a new and important tool for plant virus research, and its application is continually being developed and improved. By means of the serological reactions, latent virus infections can be readily demonstrated. This is of practical importance for several economically important crops, as in the building-up of virus-free stocks of potatoes and flower bulbs, for example. Furthermore, by means of this technique, relationships can be shown to exist between viruses which would otherwise never have been suspected of a close connexion. This, in turn, may throw light upon some problems which have long puzzled plant virologists. The ability to establish serological relationships between viruses gains an added importance in view of the unreliability of cross-protection tests which is only now being realized. Up to now all this information has been scattered widely throughout the plant virus literature, or given necessarily brief treatment in text-books of general plant virology, so that Dr. Matthews is to be congratulated on his book which, for the first time, gives a descriptive survey of plant virus serological methods together with practical instructions.

After a brief introduction, there is a description of the methods of preparing the viruses for injection into the rabbit and for collection of the antisera. The types of serological tests are next explained, followed by an account of the routine testing for virus infection. In routine work, the precipitation test is of particular value when large numbers of plants have to be examined for the presence of a latent virus infection; this is especially true in certification schemes for vegetatively reproduced plants. With modern developments this technique can now be applied directly in the field by persons without much training in the subject.

Chapter 5 gives a good description of the serological tests used for determining relationships among plant viruses. In Chapter 6, in his account of the precipitation reaction, the author includes some of his own original work. Certain plant virus nucleoproteins, which can be isolated in large quantities, are relatively homogeneous from the serological point of view, as compared with other protein antigens. The virus of turnip yellow mosaic is particularly suitable in this respect, and some aspects of the precipitation reaction are illustrated by new data obtained with this virus. These experiments have implications extending beyond the field of plant virus serology and should interest the general immunologist.

Chapter 7 deals with the antibody content of sera; this has not a general application to plant virus work, but it is useful on occasions. For example, titre measurements on antisera showed that the 'top component' of turnip yellow mosaic virus, which has no nucleic acid, was much less efficient in stimulating antibody production than the 'bottom component' which is the nucleoprotein. In Chapter 8 the methods for estimating virus concentration are discussed, the precipitation reaction providing a rapid and convenient means towards this end. The specificity of the reaction allows virus to be estimated in the presence not only of plant impurities but also of unrelated viruses. In Chapter 9 the cross-absorption procedure is dealt with which can be used for estimating degrees of relationship between viruses, and in Chapters 10 and 11 experiments with mixtures of viruses and strains of viruses, and the causes of failure to obtain positive serological tests, are discussed. With regard to the last point, antisera have been prepared for about thirty plant viruses or groups of virus strains, but there are still 200 or more viruses to which serological methods have not yet been applied. In some cases repeated attempts to obtain antisera have resulted in failure; this may be in part due to lack of concentration of the virus, so that new methods of virus concentration may have to be devised. Then, of course, a large number of viruses are not mechanically transmissible and this greatly complicates the study of their serology.

This book is a valuable contribution to the study of plant viruses, and should be read by all plant virologists and by immunologists in general. The different procedures and their pitfalls are carefully and lucidly explained, and the illustrations and tables are excellent. The electron micrograph, in the frontispiece, shows dramatically how, in a mixture of viruses, the antiserum aggregates only the virus against which it was prepared. Kenneth M. Smith

THEORY OF INSTRUMENTATION

Instrument Technology

By E. B. Jones. Vol. 2: Analysis Instruments. Pp. xi+208. 40*s*. Vol. 3: Telemetering and Automatic Control. Pp. x+198. 40*s*. (London: Butterworths Scientific Publications, 1956–57.)

It is always a pleasure to read clear prose, and quite apart from the technical merits of these volumes, one is impressed by their lucidity. In these volumes, as in their predecessor, the author chooses as his audience the instrument mechanics of industry. Anyone interested in his subject can sympathize with the author in his task of selecting material and restricting explanations in a field where to-day's success may be to-morrow's museum exhibit. Mr. E. B. Jones is to be congratulated on providing a theoretical background to efficient instrument use and maintenance, even if it is possible to differ from the publisher's announcement which rather suggests the work is a maintenance guide. Obviously, nothing can replace the manufacturer's manual and still remain of general interest.

The second volume describes the principles and applications of measurements based on the composition of fluid streams or samples, and thus continues the treatment of pressure, level, and temperature measurement which was covered in Vol. 1. In this volume the very clear diagrams, and the short accounts of physical and chemical principles, are very attractive. The third volume attempts to show the application of automatic control to processes where variables are measured by the means examined in earlier volumes. In the discussion on telemetering, and especially of automatic control, all material appears to have been tested by the yardstick of usefulness, so that a well-grounded, but general, treatment results.

One can recommend this book for the training of instrument mechanics, since the level of knowledge that it will provide as adjuncts to the practical skills of installation, maintenance and 'trouble-shooting' can only result in a more intelligent use of instruments and automatic control devices. T. K. Ross

ELECTRONICS DIGEST

Handbook of Industrial Electronic Control Circuits

By John Markus and Vin Zeluff. Pp. xv+352. (London: McGraw-Hill Publishing Company, Ltd., 1956.) 66*s*.

The Cathode Ray Oscilloscope

Circuitry and Practical Applications. By J. Czech. Pp. xii+340. (Eindhoven: N. V. Philips' Gloeilampenfabrieken; London: Cleaver-Hume Press, Ltd., 1957.) 57*s*. 6*d*.

A critical survey of some aspect of technology is no mean task when undertaken by an individual author, if his book is to be reasonably up to date at the time that it appears. There are other and complementary ways of presenting accounts of current practice, either through collected digests of articles that have appeared in the technical periodicals, or from the collective experience of a company specializing in a particular field.

The book by Markus and Zeluff might be described as 'articles of lasting interest, skilfully digested' from the well-known journal *Electronics*. Some 350 articles that appeared during 1948–55 are included in a volume weighing 3 lb., a worth-while reduction from the 6 ft. shelf and 200 lb. of the original magazines.

Czech's book for users of the cathode ray oscilloscope is translated from the German, and is one of the extensive series of Philips's technical and scientific publications. Like many titles in the series, it is closely related to the experience and products of that Company.

While both books lack the critical approach to first principles so valuable to the advanced designers of equipment, they will be helpful to the wider circle of technicians interested in particular applications. The selection from *Electronics* has been classified under such headings as amplifier circuits, capacitance control, counting circuits, measuring circuits, metal detectors, motor control, oscillators, photoelectric controls, temperature control, timing, power supply and transistor circuits. A rather full index has been added, and provides a useful cross-reference between articles containing related material; the original reference is given in each case. As the title suggests, the emphasis is upon industrial control applications, written at the consistently practical level of the journal in which they appeared.

The user of cathode ray oscillographs will find the second book helpful, particularly because of the large number of oscillograms used as illustrations. It is not recommended as a 'first reader' on the subject, but is valuable for being written from a point of view different from the several English standard works. Its origin is most evident in the bibliography, and in the illustrations of instruments and circuits of one particular manufacturer. There are excellent sections on general measuring technique in bridge circuits, for phase and frequency measurement, and for practical work on fluorescent lamps, camera shutters, flash bulbs and television receivers.

Neither book deals with the preferred functional circuit, a concept that would greatly simplify the pursuit of conventional circuits and reduce them to system-design, by building up an assembly of functional circuit 'bricks'.

Whether or not it is worth while using this approach to clear away retrospectively the profusion of detail in circuit design is in question for thermionic circuits, but it should be done for transistor circuits. The treatment of transistors in the first book extends only to the end of 1955, but is an excellent guide of what is to come, as semi-conductors are particularly suited to industrial applications. The second book looks backward rather than ahead in its field, and transistors are not mentioned, although they have made possible a significant future development, the miniature, portable, earth-free oscilloscope.

DENIS L. JOHNSTON

FLAME SPECTROSCOPY

The Spectroscopy of Flames

By Dr. A. G. Gaydon. Pp. ix+279+6 plates. (London: Chapman and Hall, Ltd., 1957.) 50*s*. net.

FROM the earliest times of recorded observations of matter, flame and fire have occupied a place of particular interest and importance, being so obviously remarkable in nature that they were frequently regarded as constituting a principle, or element. In the early nineteenth century it became clear that flames were generally to be associated with very rapid chemical reactions, usually of combustion, and attempts to understand them, on the basis of the characteristic light emitted from them, commenced. Serious attempts of this kind have had to await the development of the application of wave mechanics to spectroscopic data, which allowed of the analysis and identification of the spectra of short-lived radicals such as, for example, C_2, CH, OH, which appear in many common flames. The next step is to deduce the part played by such radicals in the physicochemical processes occurring in flames, as part of a general scheme of elucidation of the detailed reactions of combustion.

A major part has been played in these studies in recent years by Dr. A. G. Gaydon, the author of the work under review. From time to time Dr. Gaydon has published monographs relating to the physics and chemistry of flames, which have been distinguished by their scope, their presentation of conflicting theories or points of view in a fair-minded way, and their ability to stimulate further work of importance. The present volume is no exception to this, and like the previous ones, is also most valuable for the large number of useful practical hints to workers in the field.

The book opens with a number of introductory chapters on methods of studying flame spectra, on techniques for obtaining special types of flames, such as diffusion and low-pressure flames, and on the elementary theory of atomic and molecular spectra. The last of these, while by no means supplying all the spectroscopic knowledge required by an intending worker in the field, is nevertheless a useful introduction.

The next three chapters deal, broadly, with accounts of the electronic spectra of hydrogen, carbon monoxide, and hydrocarbon flames with oxygen or air. They provide very complete descriptions of the observed features, with some discussion of whether the spectra show chemiluminescence (that is, non-thermal excitation), and of whether the concentrations of emitters are in excess of those to be expected for thermodynamic equilibrium. For example, a typically balanced account of the various views of processes of reaction in carbon monoxide flames is given. A further chapter discusses the analysis of spectra so as to obtain the effective translational, rotational, vibrational, etc., temperatures, understanding of which is required if the complicated distribution and exchange of energy between various types of molecule and degrees of freedom occurring in flames is ever to be solved in detail.

In further useful chapters the book deals with infra-red emission from flames (a rather neglected topic), the correlation of spectroscopic results with processes of reaction (including an account of carbon formation in flames), and industrial flames and engines. The book ends with an interesting account of various unusual flames, in which oxides of nitrogen, halogens, compounds of sulphur, etc., take part, and with a brief discussion of spectrophotometry of trace additives, which is itself beginning to throw light on the chemistry of flame reactions.

This is a most valuable book to all those working in any field which has points of contact with the study of rapid reactions of simple molecules. It may be that spectroscopic studies tend to emphasize the role of a small number of rather special free radicals and molecules, but it must be agreed, with the author, that "emission of light is the most distinctive property of a flame and must surely be capable of giving much information about what is happening".

THE BIOLOGY OF AGEING

Ciba Foundation Colloquia on Ageing

Vol. 2: Ageing in Transient Tissues. Edited by G. E. W. Wolstenholme and Elaine C. P. Millar. Pp. xi+263. 36*s*. net. Vol. 3: Methodology of the Study of Ageing. Edited by G. E. W. Wolstenholme and Cecilia M. O'Connor. Pp. x+202. 32*s*. 6*d*. net. (London: J. and A. Churchill, Ltd., 1956–57.)

The Biology of Ageing

Edited by W. B. Yapp and G. H. Bourne. (Symposia of the Institute of Biology, No. 6.) Pp. xiv+128. (London: Institute of Biology, 1957.) 25*s*.

REPORTS of the various symposia and colloquia, especially on endocrinological subjects, which have been organized by the Ciba Foundation, are by now widely known and appreciated. A series of colloquia on ageing is one of the more recent activities of the Foundation, and Volumes 2 and 3 provide the material which was presented at two meetings of gerontologists in July 1955 and July 1956.

Volume 2, which is devoted to a study of the ageing of component tissues of the body whose span of life is shorter than that of the whole animal, might at first glance be mistaken for one in the series of endocrinological symposia; for many of the papers deal with the growth and development of tissues concerned with reproductive processes in a fairly narrow endocrinological context. Thus, among various aspects of ovarian function, Sir Solly Zuckerman defends the thesis that oogenesis is a process that comes to an end at, or about the time of, birth, and deals critically with recent observations which purport to resuscitate the other view that neoformation continues into adult life, while Dr. Williams and Dr. Rowlands discuss the life, growth and fate of the large ovarian follicles and the corpus luteum respectively. Other mainly endocrinological contributions describe experiments concerned with such diverse subjects as the tissue culture of fœtal reproductive tracts and the study of the human testis with the electron microscope. The placenta is an excellent example of a transient tissue, and a further group of papers describe the morphological and biochemical changes in the organ during pregnancy. Dr. Villee thought that there was no evidence for any senile change in function which could be used to explain the onset of labour, and felt that the placenta was still quite active metabolically at the end of its life. A comparable conclusion came from Prof. Huggett, "that there is evidence that its 'efficiency', certainly for some functions, is increased in its old age; in fact, it might be said to be abruptly expelled in the prime of life".

Other papers by Dr. Mollison and Dr. Lovelock discuss what happens to the red blood cells to bring their life to such a rapid end, and what could be done to prolong their survival in storage. Age changes in the sweat glands of the human female, the factors controlling growth of the antlers in deer, and finally a botanical paper on the metabolism of senescent leaves, are titles which give some indication that, on this occasion, the limits of the definition of ageing were very widely stretched, perhaps to the extent of causing a lack of cohesion in the contents of the volume.

Contributors to the third colloquium on the "Methodology of the Study of Ageing" related their papers more closely to a single general theme. The study of ageing is of such relatively recent scientific respectability that workers in the field are acutely conscious of the need to agree on the basic definitions of their subject and on the limitations of various methods for studying the problem. At present they are more aware of the needs than confident that they have found solutions. It is clear that no one was sure about the level of organization at which ageing can be studied most profitably. Some thought that the comparative approach in studying whole populations had been badly neglected, whereas others discussed the ways in which ageing in separate organ systems or in individual cells might provide the important clues. Clinicians at the meeting were perhaps unnecessarily humble in believing that studies on human beings were less likely to be valuable than those of experimental workers on the mouse or the hamster.

The latter part of Volume 3 is taken up with a discussion of the psychological aspects of ageing and is notable for an excellent account by Welford of the problems which face those who want to understand the reasons why the work performance of human beings changes as they get older. Much of what he had to say about the design of experimental studies in psychological problems is very relevant to the design of experiments on animals for other gerontological purposes.

"The Biology of Ageing" summarizes the contributions to a symposium, organized by the Institute of Biology, which was intended for a much wider audience than is to be found at the Ciba Foundation. The papers cover all aspects of ageing from the demographic aspects in human populations to ageing in bacteria and higher plants. Several of the authors whose papers appear in the Ciba Colloquia are also represented in this volume, and some of them say little that they have not said elsewhere. The volume does, however, bring together contributions which should satisfy the many non-specialists who want to know how the subject is developing without wishing to immerse themselves in the details of experimental work which are to be found in the Ciba Colloquia.

P. L. Krohn

CHEMISTRY AND LIFE

A Symposium on the Chemical Basis of Heredity

Edited by William D. McElroy and Bentley Glass. (Sponsored by the McCollum-Pratt Institute of the Johns Hopkins University, with support from the Atomic Energy Commission.) Pp. xiv+848. (Baltimore, Md.: The Johns Hopkins Press; London: Oxford University Press, 1957.) £5 net.

This book describes in great detail the remarkable discussion of the chemical basis of heredity held in 1956 at the Johns Hopkins Institute. Almost every aspect of the problem of heredity was discussed and the very wide extent of the matters under survey is shown by the fact that Dr. Bentley Glass occupies no less than 77 pages in his summary of the whole symposium.

Original work is described in eight chapters which are subdivided into sections with the various discussions within the sections. The chapters concern "Cellular Units of Heredity", "The Role of the Nucleus", "Nucleic Acids and Associated Structures in Cell Division and Protein Synthesis", "Nucleic Acids—as Transforming Agents", "Viruses as Bearers of Heritable Characteristics", "Nucleic Acids—Chemical Composition and Structure", "Synthesis of Nucleotides and Nucleic Acids" and "Mechanism of Duplication". In this book all the papers are written with great clarity and are frequently illustrated by photographs and diagrams. For special mention one would point to the discussions on the nucleus and on the synthesis of proteins, the various aspects of nucleic acids as transforming agents, where the most astonishing discoveries are being made, and the outstanding work of Fraenkel-Conrat and his colleagues on the nature of viruses reconstituted from protein and nucleic acids. In addition there are discussions on the structure of deoxyribonucleic acid, particularly the Crick–Watson double helix, the polynucleotide biosynthesis of Ochoa and the biosynthesis of nucleic acids in some microbial systems. Delbruck's mechanism of deoxyribonucleic acid replication and the molecular basis of genetic recombination in phage are both remarkably good chapters.

The discussions of the various papers have been well recorded and form some of the most interesting reading in the book. From this conference it is apparent how much structural and physical chemistry are adding to knowledge of the biology of genes, chromosomes and studies in heredity generally.

The organizers of the symposium are to be congratulated on getting together such a wealth of talent; and the authors have done an excellent job in interpreting their ideas and latest discoveries. Every geneticist and biochemist will need to possess this book.

M. Stacey

THE FARM LIVESTOCK RESEARCH CENTRE OF THE ANIMAL HEALTH TRUST

By DR. W. R. WOOLDRIDGE
Scientific Director of the Trust

IN opening the new Farm Livestock Research Centre of the Animal Health Trust at Stock in Essex on Friday, December 6, H.R.H. Prince Philip, the Duke of Edinburgh, said: "There are three reasons why I am very pleased and delighted to be able to visit, open and look round these Animal Health Trust Laboratories. As you have just heard, I do not believe in half measures, and so I am president of the Royal Agricultural Society, president of the British Dairy Farmers Association and president of the Smithfield Show, and all of them are vitally interested in the health of farm animals. It also gives me an opportunity in the capacity of president of these three organizations and also in my personal capacity to express our admiration and appreciation of all the work that is done by the Animal Health Trust in all their laboratories in different parts of the country for the domestic animals of this country and, of course, animals all over the world.

"The third reason is because I am personally quite interested in farming and livestock generally and also because I am fascinated by all kinds of research. I like to see these ingenious techniques that are used to solve rather complicated problems. I like the atmosphere in a research establishment—the pleasure and excitement whenever some useful bit of work has been achieved after a great deal of hard work. I believe that in this world where we think that we know everything and we think that we can do everything it is sometimes good for the soul to be reminded how much we do not know, and one of the best places to find out is in a research laboratory.

"In this place there will be plenty to do—there is no doubt about that—for the prevention of disease and sickness and suffering in animals and also to help agriculture in the commercial sense. Disease in farm livestock is supposed to cost farmers something like £70 million a year, and so any investigation into disease and methods of cure and prevention is of the first importance. But there is an enormous gap between actual sickness on one hand and what one might describe as vigorous health on the other. There are all sorts of things in that gap. Infant mortality among human beings is something like 2 per cent; in farm livestock it is anything between 15 and 20 per cent. That is not an actual disease, but it is also not good health. Then there is infertility, that is not necessarily a disease, but there is something not exactly right, and in farm livestock in this country it is becoming rather a problem. A great many farm animals are becoming worn out sooner than they ought to—their productive life is not as long as it used to be. We do not know why strange things happen when we change the diet. We know some of the things that happen, but we do not know other things that happen. We do not know how the treatment of feeding stuffs with different things will affect the people who eat the animal products. I hope these and many other things will be investigated that are in the capable hands of Dr. Sellers and his helpers in these laboratories. I am quite sure they will soon be responsible for many, I hope, fruitful developments.

"I would also like to add my appreciation of the work and support that is being given to this effort by the Boreham Institute and their generosity, and I hope for their sakes also we may see some fruitful developments".

This Centre is one of four established by the Animal Health Trust—the others being organized also on a species basis and devoting their energies, respectively, to horses, dogs (and cats) and poultry. The Equine and Canine Centres are at Newmarket, and the Poultry Research Station, which is now an independent entity jointly supported by the Agri-

Fig. 1. Lilystone Hall, Farm Livestock Research Centre, Stock

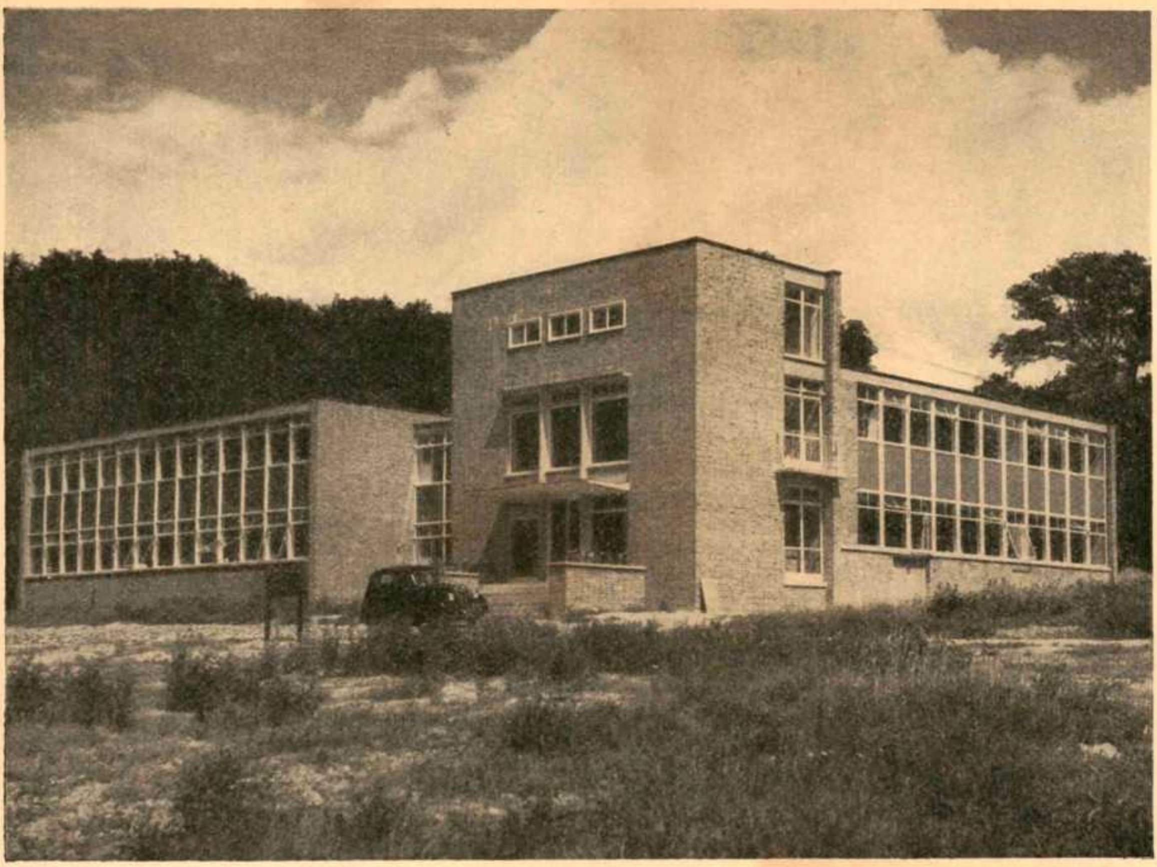

Fig. 2. New Laboratory Buildings of the Farm Livestock Research Centre

cultural Research Council and the Animal Health Trust, is at Houghton, Huntingdonshire.

The Trust is a unique organization, in that it is entirely independent ; it was founded at the end of 1942 and has maintained itself by voluntary subscriptions from owners of animals, from the general public and from organizations interested in animals. Up to date it has raised more than £1 million, which has been spent in carrying out its aims, namely to assist in the field of veterinary education and to promote researches into disease of animals and the relief of animal suffering. On the educational side it assists needy veterinary students of merit to complete their studies at the universities and makes postgraduate awards to those desiring to enter research or academic careers. It has awarded more than one hundred undergraduate studentships and more than eighty postgraduate scholarships and fellowships at a total cost of more than £100,000.

The Farm Livestock Research Centre, like the other stations, has an entity of its own, although they all come under the ultimate supervision of the scientific director of the Trust, who is advised by a Scientific Advisory Committee. Dr. K. C. Sellers is the director at Stock. The scientific staff at the moment is small, including Dr. Williams Smith as bacteriologist ; Mr. G. Skulski, pathologist ; Mr. A. L. Ogden, in charge of field surveys ; Mr. C. G. Ashton, biochemist.

The new laboratories, which will allow for some increase in the scientific staff, have been erected by the Boreham Trust, which, in addition to paying for these new buildings, has let the whole of the Lilystone Hall Estate, comprising a mansion and 37 acres, to the Animal Health Trust at a peppercorn rent (Figs. 1 and 2). The animal houses, few in number at the moment but allowing plenty of room for later development, are of a type which will permit them to be adapted fairly readily for use with different species of animals.

As with the other research centres of the Trust, the scientific staff maintains effective liaison with the farmer or other animal owner, as it is part of the policy of the Trust to employ scientists who have in addition to their own specialist experience a reasonable knowledge of the management and husbandry methods used with the species they are studying. A Livestock Advisory Committee composed of representatives of the major livestock organizations in Britain advises the director.

One of the major developments at this Centre is the carrying out of surveys in connexion with various diseases of livestock. Dr. Sellers has himself carried out a survey in east Yorkshire on the diseases of sheep, paying particular attention to losses in pregnant ewes. This survey is being continued and followed up in the laboratory.

Mr. Ogden is making a thorough survey of bovine infertility in the eastern counties in co-operation with the Milk Marketing Board. He is in close touch with the Board's progeny-testing schemes and artificial-insemination centres, and the animals, chosen at random, under his direct supervision include 3,000–4,000 cattle from some two hundred herds. Wherever possible, animals culled from these herds will be followed up in the abattoir and, where necessary, in the laboratory.

A third survey is being planned in connexion with losses in pigs. This survey is being arranged in conjunction with the staff of four large pig farms and will include several thousand animals.

It is hoped that these surveys will provide useful information and perhaps pointers to closer study of more defined problems, such as the causes of losses during early pregnancy, or during early life from birth to weaning.

The work of the Bacteriology Department is at present largely concentrated on a study of the scouring condition in calves and young pigs. The investigations have revealed that bacteria involved in the scouring condition may develop a resistance to antibiotics used in general management and as feeding additives—a fact which can have a considerable bearing upon the therapeutic use of these drugs. A technique has been devised whereby, from examination of dung samples sent in from farms, an assessment can be made within a period of only six hours, and advice given as to the best treatment for affected animals.

This work has so far been carried out mainly with *Bact. coli*, but it is being extended to other pathogenic organisms of the alimentary tract, including certain anaerobes.

Work is also continuing on Johne's disease. Following earlier work whereby a medium was devised for the more rapid culture of the Johne's disease bacillus, the presence of these microbes in various organs and tissues of the body is being examined, and useful information is being obtained which may throw light upon the route and method by which the organism gains access to the body.

Pathological work of the Centre is concerned mainly with examining material obtained from the surveys and other experimental work at the station.

In the Biochemistry Department preliminary work has been carried out upon an investigation of the blood serum proteins of cattle, sheep and pigs. The work has so far been done mainly with cattle, and the technique of examination is that of electrophoresis using specially prepared starch gels. As a result of this fairly extensive examination, it has been shown that the serum proteins of cattle fall into five patterns when examined in this way, and it has further been demonstrated that these patterns have a hereditary basis. The work is being extended to see whether, in addition, the patterns are linked in any way with such economic factors as the butter-fat or the solids-not-fat content of milk. Theoretically, it would appear that there should be a sixth pattern, and as no evidence of this has been obtained it is deduced that the mating which would give rise to this pattern is also linked with a lethal factor.

In the future it is hoped to increase the scientific staff and investigate other problems of importance to livestock farming. Certain *ad hoc* problems are already being examined, such as the treatment of bovine ringworm and the part played by iodine and vitamin A in the growth and possible disease of piglets. It is not intended, however, that this Station shall become a huge one, although there is still room for improvement which will, of course, in an organization such as the Animal Health Trust, depend upon the support it receives from livestock owners and other bodies interested in agriculture.

SCIENTIFIC OBSERVATIONS OF THE ARTIFICIAL EARTH SATELLITES AND THEIR ANALYSIS

THE advent of the Russian Earth satellites occurred so suddenly that few preparations had been made for observing them. Until July 1957, no information was available about the frequencies which were to be employed in their radio beacons. The chosen American frequency of 108 Mc./s. had been known for some time, but it was also known that the inclination of the proposed American orbits would not exceed 40°, so that it would be very difficult to make observations from stations in Britain. Considerable interest was therefore displayed when the Russians announced that their satellites would circulate in orbits at inclinations near 60°, though no detailed preparations for observation were made before the conference on rockets and satellites held under the auspices of the International Geophysical Year in Washington during September 30–October 5. It was known that a Russian delegation would attend, and it was hoped that further useful details would be forthcoming from them. In the event, the announcement of the successful launching of the first Earth satellite came during the last evening of the conference—it was announced to the conference delegates by Dr. L. V. Berkner, the American organizer of the conference, at a cocktail party, given by the Russian delegates in the Soviet Embassy in Washington.

Methods for radio, visual and radar tracking were hastily improvized. In Britain a remarkable amount of scientific work has been carried out by a great number of observers in universities and Government departments as well as by amateurs. Because of the wide range of techniques employed and the need for co-ordination of effort, a discussion was arranged by the Royal Society and was held on November 29. Papers were presented by representatives of the Cavendish and Mullard Laboratories at the University of Cambridge, the Jodrell Bank Station of the University of Manchester, the Royal Aircraft and Royal Radar Establishments, the B.B.C. and Post Office Engineering Departments, the Nautical Almanac Office, the Admiralty Signals and Radar Establishments and the Radio Research Station. Dr. J. Heywood also contributed to the discussion an account of the work done by the British Astronomical Association and the Radio Society of Great Britain. In addition to these British contributions, there was special interest in a paper presented by Dr. L. Jacchia of the Smithsonian Observatory at Cambridge, Massachusetts, on the work done in the United States on the computation of orbits for the satellites.

Much experience has been gained from the work on the first two satellites which will be of great value for future work in this field. It is now quite clear that radio tracking, while not suitable for very precise determination of satellite orbits, is quite essential as an adjunct to the use of more precise methods involving optical or radar techniques. The Russian choice of frequencies of 20 and 40 Mc./s., much lower than the American, was criticized initially because of the relatively large tracking errors introduced by the ionosphere. Experience has shown that, in fact, the accuracy is good enough to provide predictions of value for optical and radar observers, while the sensitivity to ionospheric effects can be used with great advantage for studying the structure of the ionosphere. However, it is important that the precise methods be brought to bear before failure of the radio allows the satellite to be lost.

It has been established also that optical observation of a satellite as small as the first one is a very difficult matter. This satellite seems rarely to be brighter than a sixth-magnitude star. Very good seeing conditions are required in order to observe it during the brief intervals at dawn and twilight when it is illuminated by the Sun. It was fortunate, therefore, that the rocket case which accompanied the first satellite was a very bright object when illuminated, equivalent to a star of magnitude − 1.

Because of the difficulty of optical tracking and the failure of the batteries supplying the power for the radio beacons (after three weeks for the first satellite and one week for the second), special emphasis was placed on the importance of radar tracking. The world's largest radio telescope at Jodrell Bank and also the 45-ft. diameter instrument at the Royal Radar Establishment were used with much success. In both cases the equipment was built primarily for radio-astronomical studies, and rapid improvization was necessary to fit them with reflexion radar.

The potentialities of the radar methods are considerable, and it is fortunate that two telescopes are available with such differing characteristics. The smaller, 3,000 Mc./s. telescope should be capable of detecting the small satellite at a range of 1,000 miles, and the short pulse-length (5 μsec.) gives the range to a precision of 1 km. The angular accuracy is better than ½°, and the short-wave beam is barely affected by ionospheric refraction. Further, spurious reflexions from meteor trails, which are a major annoyance in using pulses of lower frequency, are greatly reduced. However, the narrow beam width, ½°, makes searching for the satellite a long process unless its position is already fairly well known, and in fact so far the small satellite has not been observed with this instrument. Here the larger telescope, operating on frequencies of 36 and 120 Mc./s., had the advantage. Though the range on 36 Mc./s. was considerably less than that of the 45-ft. instrument, the beam width of 4° semi-angle was a great asset when searching. Radar is also of special value in the last stages of a satellite's life, and the interesting possibilities should the satellite leave a meteor type of ionization trail were emphasized.

The radar methods provide a means of determining the reflecting area of the satellite. For the rocket, a figure of 10 m.^{2} is obtained, while for the sphere it is about ½ m.^{2}. This is consistent with rocket dimensions of about 4 ft. diameter and 25 ft. long, but there appears to be some discrepancy between the drag to be expected for such a body randomly orientated and the drag actually observed. The large size of the rocket body is supported by the visual observations, and it has been suggested that the low drag is to be accounted for by the presence of sufficient aerodynamic stability to keep the rocket moving head-on to its direction of motion.

Results obtained for the orbits of the first satellite by the use of radio interferometers and Doppler recorders were described by Mr. M. Ryle (Mullard Laboratory, Cambridge) and Messrs. A. N. Beresford, E. G. C. Burt and D. G. King-Hele (Royal Aircraft Establishment). The techniques employed in the observational and analytical aspects of this work have already been described in *Nature* of November 2 and 9. The accuracy attainable is sufficient to detect and check the major effects of the Earth's equatorial bulge. Normally this produces two principal effects —a precession of the plane of the orbit about the Earth's axis in a sense opposite to that of revolution of the satellite, and a rotation of the major axis in the orbital plane. At the inclinations (nearly 65°) of the Russian Earth satellites, the second effect is very nearly zero—it vanishes for orbits with inclination 63·4°. The predicted rate of precession of the orbital plane about the Earth's axis is 3·2°, which is close to the values 3·18° and 3·17° found by the Royal Aircraft Establishment and Mullard Laboratory observers, respectively.

The effect of air resistance is to reduce the period of revolution of a satellite at a gradually increasing rate. In principle, it is possible to derive information from observations of this kind about the air density and temperature at different levels of the atmosphere through which the satellites pass. Actually, an additional complication arises from the existence of an electrical drag effect due to the effect of charging up of the satellite in its passage through the ionosphere. The fact that no less than three objects of different aspect—the satellite itself, the rocket-case and the nose-cone—were put into orbit by the first launching has been of value in studying drag. Mr. Ryle explained how it was possible, from a combination of the radio observations of the satellite with the optical and radar observations of the rocket case, to make a calibration to determine the effective drag cross-section of the latter, assuming it to be spherical. Thus in the first week or so the rate of change of period per revolution was 1·84 times greater for the rocket case than for the satellite. It seems that the satellite separated from the rocket case at a relative velocity of 186 cm./s. in a direction opposite to the orbiting motion. It thus fell to a lower altitude and commenced orbiting more rapidly, very soon overtaking the case. Soon, however, the greater drag on the case reduced its altitude and caused it once again to overtake the satellite.

Probably the most prominent feature of the discussion was the clear need for accurate orbit data. The radio methods can give apparent position with considerable precision. Thus the interferometers give apparent direction to 1 minute of arc, while the Doppler method gives the time of nearest approach (electrical) to a few milliseconds. That these results are very far from giving the true position can be judged from the fact that the time of nearest approach given by the 40 Mc./s. signal may differ by many seconds from the time given by the 20 Mc./s. signal, and signals may be received from beyond the horizon.

The discouragement of orbit-computing with data containing some material of doubtful reliability was clear from Mr. D. H. Sadler's account of the excellent work done at the Nautical Almanac Office. At Herstmonceux every observable transit had been observed. To be useful, position data should be accurate to

1/10° and 1/10 sec. time. Ten times this precision is required to derive useful information from the periodic deviation from ellipticity caused by terrestrial oblations, and for geodetic purposes another order of magnitude in precision is necessary.

Dr. Jacchia described the computational procedures used at the Smithsonian Institution, where they have the large *IBM* 704 type of electronic computer. He had ten good optical observations of the sphere and seven of the nose cone. The following expressions were given for the position of the components of the first satellite at time t; α is the right ascension of the ascending node and t_n the time of nth crossing. Time is in year days (that is, Jan. 1, 1957, $t = 0$; Oct. 7, $t = 280$).

Sputnik 1:

$$\alpha = 334{\cdot}3° - 3{\cdot}058° (t-280) - 0{\cdot}00408°(t - 280)^2$$

Rocket:

$$t_n = 282{\cdot}82058 + 0{\cdot}0686222n - 1{\cdot}47721 \exp 0{\cdot}00134n - 1{\cdot}769 \times 10^{-5} \exp 0{\cdot}0102n$$

Sphere:

$$t_n = 277{\cdot}87138(\pm 0{\cdot}00025) + 0{\cdot}0668120(\pm 0{\cdot}0000036)n - 8{\cdot}84 (\pm 0{\cdot}12) \times 10^{-7}n^2$$

Nose cone:

$$t_n = 277{\cdot}87224 (\pm 0{\cdot}00013) + 0{\cdot}0667072(\pm 0{\cdot}0000023)n - 6{\cdot}007 (\pm 0{\cdot}079) \times 10^{-7}n^2$$

The right ascension of the ascending node for *Sputnik* 2 was given as:

$$\alpha = 306{\cdot}7° - 3{\cdot}18° (t - 289)$$

The probable errors for the present position of the components emphasize the necessity of obtaining accurate data while the radio transmitter is still operative. If inadequate precision is attained during this phase, the satellite may be lost, as has occurred with the sphere, and optical and radar equipment may have much difficulty in finding it. At the time of the conference, a few kinetheodolite observations had been made in Australia, and at the Royal Aircraft Establishment it is intended soon to use kinetheodolites to give a precision of 1 msec. in time and 30 sec. of arc; but on the whole, in Great Britain especially, there has been a paucity of precise data.

The great benefit to ionospheric research of a pair of radio transmitters circulating within the F-layers was very evident. Much data have been accumulated, though of necessity interpretation lags behind. Indeed, inadequate orbit figures may reduce the value of some of the radio data. From the first, the B.B.C. carried out precise monitoring of all the telemetry and radio beacon signals. Several false starts to the Doppler frequency – time curves were noticed, which suggested 2½, 1½ and ½ hop-modes of propagation by ionospheric reflexion.

A somewhat similar phenomenon had been observed by the Post Office Engineering Department, a considerable portion of a Doppler frequency drop having occurred while the satellite was still 2,000 miles away. This was tentatively attributed to reflexion from some patch of intense ionization near to the satellite.

Using a wide-aperture high-frequency direction finder, the Admiralty Signals Establishment observed the satellite over global distances at night. Propagation, it was suggested, might be by a leaky wave-guide mode in the ionosphere, or by a multihop system. Another ionospheric effect was evidenced in the widespread observation that the Doppler frequency appeared to rise again before the signal finally disappeared. The influence of the ionosphere was also evident in the observations made of apparent bearing and elevation at 20 and 40 Mc./s. at the Radio Research Station. It was once more evident that, before these efforts can be interpreted in detail, more accurate data on time, bearing and elevation are required.

The first satellite's transmitters were keyed on both frequencies at rates varying from 108 to 180/min. The mark-to-space ratio varied considerably, and on one or two transits a curious repetitive variation in transmitter-frequency occurred during the pulse. At times also the signals from one transmitter were received at reduced strength during the transmission of the other frequency. Several measurements of field-strength gave the beacon power as a little more than 1 watt.

A variety of types of signal fading were noticed by many observers, including those using reflexion radar. A comparison of the behaviour of signals in aerials polarized at right angles and of the relative frequency of the fading on the two beacon frequencies makes it possible to distinguish between the effect of the satellite rotation, the Faraday effect and scintillation due to ionospheric irregularities. It appears that the first satellite was rotating at about 7 rev./min.

The determination of ionospheric density by Doppler measurements, by the Faraday rotation of the plane of polarization and by refraction as given by the interferometer was discussed by Dr. K. Weekes. The Faraday effect would appear to be the most promising method, though results obtained in this way so far seem to give values for electron number per unit area column in excess of those obtained by conventional radio probing.

R. L. F. BOYD

THE GRASS COVER OF AFRICA

By R. O. WHYTE and J. M. RATTRAY

Agriculture Division, Food and Agriculture Organization of the United Nations, Rome

IN those regions of Africa in which tsetse fly is not a limiting factor, domestic livestock play an important part in the economy of both European and African agriculture, and their grazing is provided almost entirely by the natural vegetation. It is therefore essential to have information on the ecological status and behaviour of that vegetation and particularly of the grass components, as a basis for what has come to be called the ecological management of grassland, in relation to its most efficient utilization and optimal productivity.

There are three main stages of the mapping of grazing lands and grass associations: (1) a physiognomic map of vegetation made by plant geographers; (2) a generalized map of the grass associations; (3) detailed studies of botanical composition and succession made on individual grass associations and on limited areas.

The latest map of the first type is that prepared by A.E.T.F.A.T. (Association pour l'Étude Taxonomique de la Flore d'Afrique), which recognizes, along with various types of forest and woodland, the geographical distribution of savannah, woodland savannah, xerophilous woodland, semi-desert scrub and grassland, all of which may represent a grazing resource of varying importance. The grassland ecologist and agronomist then knows where the grasslands are; but he must obtain further information regarding the botanical composition and ecological status and behaviour of the grass associations before he can make recommendations regarding their management.

The Food and Agriculture Organization of the United Nations has as a long-term objective the mapping of the grazing resources of the underdeveloped regions of the world on some basis which will be of value to those concerned with the improvement of grassland management and of the livestock industries which depend on them. The grazing and other resources of northern Australia are already being dealt with by Land Research and Regional Survey of the Commonwealth Scientific and Industrial Research Organization using the comprehensive survey technique involving team-work on geomorphology, geology, soils, climate, vegetation and land utilization, and leading to the recognition of land systems.

As a result of recommendations made by R. O. Whyte while acting as grassland adviser to the Government of India, a five-year reconnaissance survey of the grasslands was begun in 1954, and has already covered more than half the country. In a forest environment where climax grassland comparable with steppe, pampas and prairie (if these are true climaxes) appears to be absent, a grouping into eight main floristic grass associations has been made; the thirty or forty floristic types of grass cover which can at present be found in different parts of India are merely stages in succession produced by local variations in edaphic or other natural conditions or by the operation in varying degrees of intensity of the major biotic factors of burning, grazing and cutting.

As, apart from the broad surveys on the Australian pattern now being made by B. W. Taylor, Food and Agriculture Organization field officer in Nicaragua, the information regarding the vegetation and grass associations of Latin America is less complete than that for Africa, the Organization has concentrated first on the latter continent. J. M. Rattray has produced a map of the grass cover of the greater part of Africa on similar floristic lines to those which he had adopted earlier for his map of Southern Rhodesia.

The distribution of the main species contributing to the grass cover of Africa is a matter of considerable economic importance when it is realized that probably more than half the land surface of the continent carries a type of vegetation of which grass is an essential feature. While there already exist a number of vegetation maps of the individual territories of Africa (but only one of the continent as a whole), most if not all of these place the emphasis on the distribution of broad vegetation units which have been classified on a physiognomic or ecological basis. When a floristic classification has been used, the distribution of the woody dominants of the vegetation has generally been mapped, and the identity of the less-prominent but equally significant grass constituents has been touched on only very lightly or omitted altogether.

It is well known that the vegetation of Africa ranges from tropical forest to desert and that it includes a large number of transitional associations; it is often difficult to decide where one type starts and another ends. Rainfall and temperature are the most important factors affecting plant distribution since they are jointly responsible for the amount of moisture which the vegetation receives. When the change in climatic pattern is gradual, the change in physiognomic type is correspondingly slow, and *vice versa*. These changes in appearance are usually associated with changes in the density and nature of the tree population, the merging of forest into woodland, woodland into savannah and savannah into steppe being characteristic of the manner in which woody vegetation reacts to a gradual reduction in the amount of available soil moisture. Fire also plays a very important part in controlling the density of the tree population in Africa. Much of the more open savannah country has developed as a result of frequent burning, and when fire is excluded a tree cover tends to regenerate.

The climatic range of the grass constituents of the types of woody vegetation does not necessarily coincide with that of the associated tree species; while there may be some change in the physiognomy of the vegetation, the botanical nature of the associated grasses may remain unchanged. It has not always been possible to rely entirely on vegetation maps based on physiognomy as an accurate guide to the main grass species unless the changes in climatic pattern are sufficiently drastic to cause very considerable changes in the type of vegetation. One of the chief difficulties in compiling the Food and Agriculture Organization map has been the linking up of adjacent territories from the existing information and maps. Frequently the botanical composition of the grass cover would appear to undergo a complete change precisely on the boundary between two countries. Sometimes this may be attributed to the fact that there mountain ranges form the dividing line, for example, between certain East African territories, so that the climatic pattern on either side is sufficiently different to affect the composition of the vegetation. In other areas, however, the sudden change would appear to have resulted from differences in the technique of surveying or nomenclature, or in the interpretation of the vegetation types by those responsible for botanical surveys. In addition, the time of year when the survey was conducted is very important in relation to the dominance of the grass species in particular; surveys made early in the growing season frequently give a very different picture from those made late in the season, especially in the absence of plant counts. Where this situation arose, lists were obtained of the species which occur on both sides of the boundary; those which are characteristic of the area as a whole were ascertained, and a degree of continuity between the botanical composition of the grass cover in the neighbouring territories was thus obtained.

In the Food and Agriculture Organization map of Africa, emphasis has been placed first on the distribution of the main grass associations characterized, but not necessarily dominated, by a particular genus, and secondly, on the type of vegetation with which these are commonly found. The sixteen main types of grass associations, with a number of sub-associations which have been recognized within each main class, are as follow:

Main grass associations in Africa	No. of sub-associations	Main grass associations in Africa	No. of sub-associations
Andropogon	7	*Exotheca*	1
Aristida	8	*Heteropogon*	1
Cenchrus	2	*Hyparrhenia*	30
Chasmopodium	2	*Loudetia*	4
Chloris	1	*Panicum*	3
Chrysopogon	6	*Pennisetum*	3
Ehrharta	1	*Setaria*	2
Eragrostis	7	*Themeda*	22

The main grass associations are given in different colours (sixteen in all); these colours are entered in the map in various shadings and hatchings to indicate the occurrence of the grass type in different physiognomic formations. Thus the colour blue indicates management of lesser-known grasslands in, for of this basic blue colour represent: (1) species of *Hyparrhenia* and other grasses, forming grassland; (2) species of *Hyparrhenia* and other grasses, associated with woodland of varying density; (3) species of *Hyparrhenia* and other grasses, associated with savannah of varying density; (4) species of *Hyparrhenia* and other grasses, associated with tree steppe.

Within these types are entered a letter and number to indicate the approximate location of a particular sub-type; the thirty sub-types within the main *Hyparrhenia* type are therefore entered as *H*1 to *H*30. The accompanying text indicates in varying degrees of completeness, depending on the information available, the associated grass, tree and other species, altitude, rainfall and present management as grazing land or utilization as crop land.

These basic studies on the distribution of types of grass associations in Africa, when considered alongside the results being obtained in India and northern Australia, may be used for a number of purposes. Within the overall picture of distribution of tropical grasslands, it is expected that these studies will show a considerable degree of similarity between the types of grass cover in the great arc of lands from central, east and north-east Africa to India, and on to northern Australia. As knowledge of this type accumulates, it should be applicable to the ecological management of lesser-known grasslands in, for example, West and East Pakistan, Ceylon, Burma and the countries of south-east Asia. Since the greater part of the grass cover in the deforested areas of tropical and sub-tropical Latin America is dominated by species which may have been fortuitously or intentionally introduced from Africa, the experience obtained and the technique of mapping adopted in the preparation of the Food and Agriculture Organization map of Africa should be of great value when the Organization comes to prepare a map of the grass cover of Latin America.

From the point of view of management of natural vegetation for grazing purposes, it should be possible to transpose methods which have been worked out for one region of Africa to another with a similar type of grass cover but lacking adequate facilities for research. In the text accompanying the map it has been possible to give full details regarding management for the grass types which occur in Southern Rhodesia and Kenya, covering such aspects as the duration of the grazing season, the need for resting vegetation from time to time and the place of burning in a system of management. The ultimate objective is to be able to give this type of information for all the economically important types of grass cover in Africa. It should further be possible to use the grass map in association with soil and climatic maps to indicate the capability of various land classes for the cultivation of specific crops in fertility-maintaining rotations, bearing in mind always the optimal conservation of vegetation, soil and water.

BIOLOGICAL PRODUCTIVITY OF BRITAIN

A SYMPOSIUM on "The Biological Productivity of Britain", organized by the Institute of Biology, was held during October 4–5, in the lecture theatre of the Royal Geographical Society. It attempted to survey present and possible future production from agriculture, horticulture and forestry, from the uncultivated uplands and from rivers and inland waters of Britain. So large a subject could not be covered in detail, and some important aspects of it, notably the losses from diseases and pests, were deliberately omitted; it is hoped that these may provide subjects for future symposia.

The proceedings were opened by Lord St. Aldwyn, Parliamentary Secretary to the Ministry of Agriculture, Fisheries and Food, who said that the Institute of Biology, by providing a forum for interchange of ideas between scientists of many different disciplines, and acting as a focus of views of biologists, is of great value to the Government, which regards it as its function to encourage, assist and put on a sound organizational basis the work of the scientist in the biological field. The promotion of an efficient agriculture is a vital interest of the community, and so the elucidation by biologists of productive potential takes place in a favourable climate of opinion. How far this potential can be realized depends on economic, social, psychological and political considerations, but that does not diminish the value of asking the fundamental questions.

The first session, with Prof. H. D. Kay as chairman, dealt with limitations on production set by the available land area and by climatic and physiological factors. Prof. L. Dudley Stamp (London School of Economics) said that the pattern of land-use in Britain is remarkably stable; it is determined mainly by elevation, slope and rainfall, with soil-type as a more local influence. He advocated that classification of land to indicate its agricultural potential should in future be based on the number of standard nutrition units (each equal to 10^6 calories per annum, sufficient to support one human being in health) that can be produced per acre. Recent changes in land use, described by Dr. G. P. Wibberley (Wye College), are difficult to assess quantitatively because of the inaccuracy of the records; thus loss of farm-land to other uses, mainly urban development, in England and Wales during 1900–50 was nearly twice as great as indicated by the official statistics, and amounted to 2½ million acres. Discussion of these papers revealed disagreements about the economics of glasshouse production, emphasized that urban land is not wholly sterile—it was said to account for about 5 per cent of home food production at present, and for about 10 per cent during the Second World War—and questioned the validity of a standard nutrition unit based only on calories and ignoring quality aspects of food, especially protein content.

Biological productivity depends ultimately on factors that limit total photosynthesis per unit area of land. Dr. D. J. Watson (Rothamsted Experimental Station) showed that there is little hope of improving the photosynthetic efficiency of field crops, and as the maximal leaf area of some species is already close to the optimum for dry-matter production, the main possibility for increasing yield lies in increasing leaf area during parts of the growth period when it is small. Possible ways of doing this, such as breeding for frost resistance to permit earlier leaf growth in spring, and the use of gibberellic acid, were suggested by several speakers, and others speculated on the ideal architecture of a crop plant.

The second session, with Mr. F. C. Bawden in the chair, began with an account by Dr. H. G. Sanders (Ministry of Agriculture, Fisheries and Food) of present agricultural production in Britain, which he thought "just about right", though undeniably below the biological potential of the land. The fertility of the soil is well maintained, but drainage has been neglected. Production of good-quality beef and lamb should be increased, and this depends on improvements in production, conservation and utilization of grassland herbage.

The development of more efficient systems of husbandry calls for improved varieties of crop plants adapted to changed environmental conditions. Dr. G. D. H. Bell (Plant Breeding Institute, Cambridge) described the methods of controlled hybridization and selection used by plant breeders for producing new varieties to satisfy particular needs. Of the newer techniques, chromosome doubling has already produced commercially valuable polyploid strains of sugar beet. The chief value of mutations induced artificially by ionizing radiation or chemical treatment may be to provide new parental types for hybridization.

In a paper on expansion of animal production, Prof. M. McG. Cooper (King's College, Newcastle) agreed with Dr. Sanders that only beef and lamb production should be increased; there is already some over-production of eggs and milk. The high intensity of grassland farming appropriate for milk production may not be so effective for fat lamb or beef. Much beef production would have to be a by-product of dairying, using steers bred from dairy cows by beef bulls, and reared by more economical methods based on early weaning and the use of antibiotics. Singularly little progress has been made in the past fifty years in improving the inherent quality of farm livestock, partly because most herds and flocks are too small to be effective breeding units. British livestock are performing well below their potential, and the basic problem still is adequate agricultural education.

Some very variable estimates of productivity per man in British agriculture were put forward in the subsequent discussion, ranging from nearly £700 a year to zero or a negative amount depending on how far subsidies are allowed to enter into the sum. It was claimed that capital invested in reclamation of waste land in the lowlands would give a greater return than schemes for improving hill land. It was also suggested that soils of low productivity should be improved by using earth-moving machinery to mix adjacent heavy clays and light sands, and that more wild species of animals and plants might be domesticated.

Mr. E. M. Nicholson took the chair for the third session, which dealt with productivity of rivers, lakes and forests. Dr. J. W. G. Lund (Freshwater Biological Association, Windermere) stressed the lack of information on primary production in fresh waters; most studies considered only the phytoplankton, but in fresh water benthic plants may produce far more than the plankton. The standing crop may give a fallacious idea of the primary production, if it is not measured at short intervals. There is at present little economic interest in increasing the production of aquatic plants; on the contrary, water undertakings and some industries are concerned to keep it at a low level. In a paper on the production of fish, Mr. E. D. Le Cren (Freshwater Biological Association, Windermere) said that under intensive management fresh waters can produce large crops of first-class protein that compare favourably with agriculture in yield and economic value, but except for trout there is no market for freshwater fish in Britain. A large part of the productivity of British waters goes towards the production of eggs and milt and the rearing of fry that then die; the angler catches only a tiny fraction of the fish-flesh produced, and then returns much of it in fear of depleting the spawning stock.

Present production from forestry in Britain, unlike that from agriculture, is far from being "just about right". Mr. M. V. Laurie (Forestry Research Station, Farnham) said that per head of population it is nearly the lowest in Europe, and satisfies only 10 per cent of Britain's timber requirements. Since the War, the programme of reafforestation is falling behind for lack of sites within the narrow range between what is unsuitable for agriculture and what is unsuitable for forestry, and research is in progress to extend the planting limits that are set mainly by exposure, which prevents planting above 1,500 ft., and by depth of soil. Dr. J. D. Ovington (Merlewood Research Station, Nature Conservancy) said that forestry has ceased to be exploitation of natural vegetation, and sylviculturists are attempting to domesticate trees, just as herbaceous plants were domesticated for agriculture. How far better management techniques, introduction of new species, and breeding for desirable qualities can raise the productivity of British woodlands is doubtful, because little is known about the ecological factors that control productivity. Fertilizers may be necessary for sustained production over long periods. Growth studies on an age series of Scots pine plantations showed greater annual dry-matter production than by neighbouring agricultural crops, presumably because of the continuous leaf cover, but only a small fraction of the dry matter produced in woodland is utilized by man; controlled grazing of the ground flora might be one way of increasing it.

The discussion covered a wide range of topics including the value of leguminous ground crops in young forest, the effect of coniferous trees on soil *p*H, the influence of different tree species on soil formation, the effect of forest cover on the supply of water from a catchment area, and the possibility of using some good agricultural land for hardwood forest.

In the fourth session there were papers on water control for increased crop production, the future of British uplands and unconventional production of foodstuffs. Dr. H. L. Penman (Rothamsted Experimental Station) said that though the agricultural value of field drainage is undoubted, there are no data that give a quantitative measure of it. More than half the clay lands in England and Wales are inadequately drained. In the eastern counties, irrigation would increase production of potatoes, sugar beet and grass in a majority of seasons, but to have a significant effect on national food production a very large amount of water would have to be provided by impounding winter rain that at present runs to waste, or by importation from elsewhere in Britain.

Prof. J. B. Cragg (University of Durham) advocated a multi-purpose use of the uplands, based on ecological surveys and a classification of the capability of the land. Extractive processes such as grazing should be so arranged that the ecological complex of soil, flora and fauna retains sufficient reserves and variety to resist deterioration. In some areas fertilizer application may suffice to fit the soil for grassland or crop production; in others of lower mineral status reafforestation may be essential to restore fertility, or removal of peat deposits may expose soils capable of agricultural development.

The most extreme unconventionality in food production would be total synthesis, but Mr. N. W. Pirie (Rothamsted Experimental Station) thought this could provide only a small fraction of future food supplies, because of the scale of the industry required. The primary source of food would probably continue to be higher plants grown essentially as they grow now; but biochemical engineering, by developing ways of separating edible fractions from plant material that is not directly suitable for human consumption, may enable more productive plant species to be cultivated, and circumvent wasteful conversion by animals. As a practical example, Mr. Pirie provided samples of food containing leaf protein for the audience to taste.

In summing-up the symposium, the chairman, Prof. W. H. Pearsall, directed attention to two omissions: there had been no detailed reference to the importance of either carbon dioxide or nitrogen supplies in biological production. A biological criterion of land use was required, and he suggested that the availability of soil nitrogen should determine whether a site is used mainly for protein production or for cellulose production. The meeting finished with a general discussion which referred to water meadows, human tolerance of plant protein, the yield of mass cultures of green algæ, the carbon dioxide content of the internal atmosphere of leaves, and the advantages of mixed farming. Several speakers stressed the need for better administrative machinery to decide between competing uses of marginal land.

Two distinct problems were considered in this symposium: first, the potential biological productivity from the land of Britain, and secondly, what is desirable or practicable in the current state of economics and politics. It was made clear that present production is far short of the potential, and this is a comforting thing, because with world population rapidly increasing Britain may need to produce more food in the future. It is therefore vitally important to get information now on all possible ways of increasing yield, so that the maximum can be produced when the economic situation demands it.

A full account of the proceedings of the symposium will shortly be published by the Institute of Biology.

D. J. Watson

SMOKING HABITS AND MORTALITY AMONG WORKERS IN CIGARETTE FACTORIES

A PAPER entitled "Smoking Habits and Mortality among Workers in Cigarette Factories", by H. B. Haag and H. R. Hanmer, was read before the Section on Industrial Medicine and Surgery of the Southern Medical Association at its 51st annual meeting at Miami Beach, Florida, on November 14. The paper deals with a four-year survey of the mortality among permanent employees and retired employees in nine processing plants of the American Tobacco Company and links this with observations made by Finkner and his co-workers[1] on the smoking habits of cigarette factory employees and by Haenszel and others[2] on the smoking habits of the 'general population' of the United States.

Haag and Hanmer conclude that their study of this sub-population shows "a higher-than-average percentage of smokers and a much higher-than-average rate of smoking to be associated with greater longevity, relatively lower death rates from cancer and cardiovascular diseases and respiratory cancer rates no higher than the general population". Their results are summarized in Table 1.

The authors make two further claims:

(1) That "The existence of such a population makes it evident that cigarette smoking *per se* is not necessarily or invariably associated with a higher risk of lung cancer or cardiovascular diseases or with diminished longevity". (2) "This finding assumes added significance from the fact that no sampling error is involved in the methodology." This refers to the statement of the results, not to the first claim.

The first commendably restrained and qualified claim can in fact only be made if the second claim is true.

Table 1. Observed and Expected Number of Deaths from Specified Causes among Full-time and Retired Employees of Cigarette Plants and Stemmeries of the American Tobacco Company during January 1953–December 1956

Cause	Expected No. of deaths	Observed No. of deaths	Ratio: expected to observed
All causes	350	241	1·45
Cancer—all forms (140–205)	61	47	1·30
Cancer—respiratory system (160–164)	10	10	1·00
Cancer of trachea, bronchus and lung, specified as primary (162)	4	4	1·00
Cardiovascular diseases (400–468)	137	104	1·32
Coronary disease (420)	82	56	1·46

Numbers in parenthesis refer to cause-of-death codes of the sixth revision of the international statistical classification, 1948, as used in "Vital Statistics of the United States"

It is one of the penalties of writing about such inflammatory topics as the alleged etiological role of smoking in the development of lung cancer that it is almost certain that irresponsible as well as responsible use will be made of any conclusions, with respect both to the influencing of personal habits and to the pursuit of wealth. Because of this possibility, the logical credentials of any investigation that appears to throw new light on the matter should be subjected to careful scrutiny.

In the paper under consideration the methods employed involve a comparison between the 'expected' number of deaths from different causes that would have occurred if the death-rates for the general population were in fact operating on the sub-section of the population under consideration, and the observed number of deaths that did in fact occur in the sub-section.

The arguments employed are based upon the partly explicit premise that the employees of the American Tobacco Company include a higher proportion of regular smokers, and that these smokers have a higher personal cigarette consumption, than the general population; and that this difference is sufficient to warrant the inference that, if it were true that smoking has the etiological effect claimed with respect to the diseases under consideration, the mortality from these diseases would, under the conditions of the study, necessarily be higher than the 'expected' mortality.

An implicit premise of the arguments is that the sub-section of the population differs from the general population, in respect of all those attributes that may render them liable to succumb to the diseases considered, only in their smoking habits, which form the subject of the investigation, and in age, sex, and colour distribution for which allowance can be made by using the appropriate specific death-rates.

Let us now examine the first premise. The reported association[3] between smoking and lung cancer is more marked than that between smoking and the other causes of death under consideration. It is therefore appropriate to use this alleged association to see what effect the recorded alteration of smoking habits[1,2] would have on the 'expected' number of deaths derived from the death-rates of the general population if the finding of Hammond and Horn accurately reflects the degree of association.

From these data and those provided by the authors it has been possible, by making certain assumptions, to calculate the factor by which the 'expected' number of deaths would have to be multiplied, because of the change in smoking habits, if Hammond and Horn's hypothesis is correct. The required factor is 1·7, so that the 'expected' number of lung cancer deaths would become 7 instead of 4 as a result of the change.

The assumptions which, in the absence of more precise information, have been made are that the lung cancer 'expectation' is derived largely from male employees (and retired employees) aged between fifty and seventy, and that the age distribution of these employees is the same as that in the general male population of the United States. If much of the 'expectation' is derived from male employees under fifty or from female employees, or if the number of male employees tail off with advancing age more rapidly than the number in the general population, the factor of 1·7 will have to be reduced, perhaps substantially.

Although the data for allowing for colour difference are not available, there is no reason to believe that this would affect the factor profoundly.

The sample size of the survey was such that 4 deaths from lung cancer were expected at the rates for the general population. Applying the conventional test of significance at the $P = 0{\cdot}05$ level, that is, $\pm 2 \times \sqrt{(\text{expectation})}$, the investigation could not have discriminated, at this significance level, between an observed value of 0 and 8. Since the hypothesis of Hammond and Horn only requires an observed value of 7, the conditions of the study are not such that it could have detected the difference of lung cancer mortality that would have resulted from the changed smoking pattern of the American Tobacco Company employees if Hammond and Horn's hypothesis were true.

This reasoning does not apply to cases of the diseases other than respiratory cancer under consideration, where a marked deficiency of the observed deaths compared to 'expected' deaths is found. These diseases, except for the unspecified ones in the group 'all causes', are relatively chronic ones. This circumstance should at once lead us to examine the second premise, and to ask whether the sub-section of the population, the American Tobacco Company employees, is in fact representative of the general population of the United States in respect of all the attributes, other than smoking habits, age, sex, and colour, that may render its members more liable to succumb to the diseases under consideration.

The study does not mention how the American Tobacco Company selects its employees, how rapid the labour turnover is, what the sex, age and colour distribution is, or how long the employees have been with the Company. Furthermore, the authors do not state that any cognizance has been taken of past employees who leave for reasons other than retirement.

If any kind of medical screening is employed, the sub-population at once ceases to be representative of the general population, and the difference may easily be such as to invalidate any conclusions that may be drawn from the application of rates derived from the general population.

In a survey covering a relatively short period of time (four years) and which is dealing with chronic diseases, this source of bias can be particularly important. The bias will become even more marked if the labour turnover is high, since there will always be a large proportion of the sub-population who have recently been admitted to it because they were found to be free from disease. Further bias might be introduced if there were a selective wastage due to employees with early signs of chronic disease seeking more suitable employment.

It must therefore be concluded that the evidence at present advanced in this paper does not warrant the claim that "no sampling error is involved in the methodology", and until further evidence can be produced to satisfy readers that the methodology is in fact valid, judgment on the first claim, that "The existence of such a population makes it evident that cigarette smoking *per se* is not necessarily or invariably associated with a higher risk of lung cancer or cardiovascular diseases or with diminished longevity", should be reserved. With regard to the specific topic of lung cancer and smoking, it would be necessary in addition to enlarge the survey considerably before the conclusions of Hammond and Horn could be refuted.

Since the topic is of considerable importance to the public health it is to be hoped that the authors will be able to provide the missing background information and to extend the survey. If it is at all possible, it would be highly desirable to extend the survey to discriminate between the different smoking categories within the American Tobacco Company employees, and to see if a mortality gradient corresponding to cigarette consumption is shown. Unless and until the survey is extended and doubts about methodology dispelled, the authors' conclusions should not be used as a guide to human behaviour.

R. A. M. Case

NEWS and VIEWS

New Year Honours List

The following names of scientists and others associated with scientific work appear in the New Year Honours list:

Baronet: Sir Harry Platt, lately president of the Royal College of Surgeons.

G.C.V.O.: Sir Stewart Duke-Elder.

C.H.: Viscount Nuffield.

K.C.B.: Dr. Harry W. Melville, secretary, Department of Scientific and Industrial Research.

K.B.E.: Maurice E. Adams, civil engineer-in-chief, Admiralty.

Knights: William R. J. Cook, deputy director, Atomic Weapons Research Establishment, Aldermaston (United Kingdom Atomic Energy Authority); Dr. Julian S. Huxley; Prof. Christopher K. Ingold, professor of chemistry, University of London (University College); Prof. Hans A. Krebs, Whitley professor of biochemistry, University of Oxford, and honorary director of the Cell Metabolism Research Unit of the Medical Research Council; Dr. Ernest Marsden, member of the New Zealand Council for Scientific and Industrial Research; John W. Worboys, chairman, Council of Industrial Design, a director of Imperial Chemical Industries, Ltd.

C.B.: Hayne Constant, director, National Gas Turbine Establishment (Ministry of Supply); J. E. Serby, director-general, Guided Weapons (Ministry of Supply); H. Tetley, deputy government actuary.

C.M.G.: A. L. P. Kirwan, director and secretary, Royal Geographical Society.

C.B.E.: P. H. Andrews, assistant secretary, Ministry of Agriculture, Fisheries and Food; Dr. C. R. Burch, Warren Research Fellow in physics, University of Bristol; A. E. Crook, principal inspector of mechanical engineering, Mines Inspectorate (Ministry of Power); Prof. H. J. Emeléus, professor of inorganic chemistry, University of Cambridge; Prof. R. H. Evans, professor of civil engineering, University of Leeds; W. N. Foster, petroleum technologist, Trinidad; D. L. Gunn, director, International Red Locust Control Service, Northern Rhodesia; H. W. Harvey, senior principal scientific officer, Laboratory of the Marine Biological Association of the United Kingdom, Plymouth; L. Hughes, deputy chief veterinary officer, Ministry of Agriculture, Fisheries and Food; Dr. C. H. Johnson, director, Materials and Explosives Research and Development, Ministry of Supply; W. E. Lancaster, lately director of veterinary services, Federation of Malaya; H. B. McCance, chairman of council, Linen Industry Research Association; Prof. P. B. Medawar, Jodrell professor of zoology and comparative anatomy, University College, London; Dr. G. A. Reay, superintendent, Torry Research Station, Food Investigation Organization, Department of Scientific and Industrial Research; Prof. I. A. Richmond, professor of archæology of the Roman Empire, University of Oxford; H. Service, lately director, Geological Survey, Malaya; G. D. Sharman, assistant secretary, Department of Agriculture for Scotland; Dr. R. W. West, principal, Battersea College of Technology; J. Wilson, director of research, British Rayon Research Association.

Mechanical Engineering in the University of Western Australia: Prof. D. J. F. Allen-Williams

Dr. D. J. F. Allen-Williams, who has recently been appointed to the chair of mechanical engineering in the University of Western Australia, is thirty-nine. He was educated at Harrow School and Clare College, Cambridge, where he took Part I of the Mathematical Tripos and then in 1939 the Mechanical Sciences Tripos. After some official civil engineering work in 1939, he was seconded in 1940 to the Air Ministry Research Establishment, Swanage (later known as the Telecommunications Research Establishment). He worked mainly on radar countermeasures and after a visit to the United States was posted in 1945 to the headquarters of South East Asia Command. He was recalled in October 1945 to become group leader in electronic instrumentation for nuclear physics at the Telecommunications Research Establishment, Malvern. In October 1946 he returned to Cambridge as a research student in the Department of Radiotherapeutics. His main work was the development of the 30-MeV. synchrotron as a radiotherapeutic instrument. By his efforts, Dr. Allen-Williams made it practicable to carry out a useful, though limited, clinical trial with a machine which was found to present a great many difficulties. In 1950 he was elected to a British Empire Cancer Campaign Junior Fellowship to continue his work on the synchrotron and its applications to radiotherapy. In 1952 he received the degree of Ph.D. (Cantab.) for a thesis on this work, and in October 1953 was appointed physicist with special reference to the applications of electronics to radiotherapeutics in the Department of Radiotherapeutics of the University of Cambridge. In November 1954 he joined the Ruxton–Paxman Group of companies to study the development of nuclear energy in industry, and in July 1955 he was appointed senior research engineer with Davey, Paxman and Co., Ltd. He has always been interested in the contributions of engineering to social betterment and the improvement of conditions of living.

Civil Engineering at Southampton :

Prof. P. B. Morice

In view of the recent and forthcoming growth in the size of the Engineering Faculty, the University of Southampton has decided to increase the number of chairs in the faculty. In accordance with this policy, the University has instituted a chair of civil engineering ; the first professor will be Dr. P. B. Morice. After taking his degree at the University of Bristol, Dr. Morice was for a time with the Surrey County Council Highways and Bridges Department. Since 1948 he has been with the Research Division of the Cement and Concrete Association, and has been for a number of years head of the Structures Research Department. His main interests lie in the fields of pre-stressed concrete and in the theory of structural analysis. The University of Southampton can look forward to the vigorous growth of the Civil Engineering Department now that it has at its head a professor with an outstanding record of research.

Geology at Exeter : Prof. Alan Stuart

The establishment of a chair of geology in the University of Exeter is a further stage in the growth of that young institution. Mr. Alan Stuart had the task of laying the foundations of a Department of Geology twelve years ago, and a measure of the success of his efforts is now his promotion to a professorship. Prof. Stuart received his undergraduate training, after service in the First World War, in the University of Durham, specializing in mineralogy and petrology under the guidance of Dr. L. Hawkes. In 1921 he was appointed to the staff of the new University College of Swansea, where for twenty-five years he was not only responsible for much of the geological teaching and the building of the Department, but also undertook part of the College administration, notably as superintendent of examinations. He thus had experience in university affairs that stood him in good stead when he assumed his duties in Exeter in 1947. Prof. Stuart's interests have been wide : he has published work on the petrology of coal, on magnetite sands, on the mineralogy of the Old Red Sandstone and of recent dune sands, and on the ontogeny of gastropod shells. More recently he has devoted special attention to optical methods in mineralogical and crystallographic analysis, and is joint author with N. H. Hartshorne of the standard work "Crystals and the Polarizing Microscope". It is a fitting conclusion to a devoted university career that Exeter should have thought it proper to appoint him to the chair.

The Royal Society : Vice-presidents for 1958

Sir Cyril Hinshelwood, president of the Royal Society, has appointed the following vice-presidents for the year ending November 30, 1958 : Sir William Penney, treasurer of the Royal Society, director of the Atomic Weapons Research Establishment, Aldermaston ; Sir Lindor Brown, biological secretary of the Royal Society, Jodrell professor of physiology at University College, London ; Sir Charles Dodds, Courtauld professor of biochemistry in the University of London ; Sir Bryan Matthews, professor of physiology in the University of Cambridge.

European Organization for Nuclear Research : Appointments

M. François de Rose, a member of the French Atomic Energy Commission, has been elected president of the European Organization for Nuclear Research (C.E.R.N.) in succession to Sir Ben Lockspeiser, who guided the Organization during its formative period and is retiring on completion of the statutory three-year term of office. Mr. J. Willems, of Belgium, and Prof. W. Heisenberg, of Germany, have been elected vice-presidents. They succeed Mr. F. de Rose, of France, and Prof. Holtsmark, of Norway. Prof. E. Amaldi, of Italy, has assumed the chairmanship of the Scientific Policy Committee, succeeding Prof. W. Heisenberg of Germany. Mr. J. H. Bannier, of the Netherlands, has been appointed chairman of the Finance Committee, in succession to Mr. J. Willems, of Belgium. Sir Harry Melville, secretary of the Department of Scientific and Industrial Research, has been appointed to succeed Sir Ben Lockspeiser as one of the British delegates to the Council of the Organization, the other delegate being Sir John Cockcroft. During 1957 the entire staff of the Organization moved into its permanent headquarters at Meyrin, near Geneva. The total number of personnel is now 598, of which about two-thirds are scientific and technical.

American Hall of Fame

Bronze busts of George Westinghouse, inventor of the air brake, and Josiah Willard Gibbs, the thermodynamicist, are to be placed in the Hall of Fame for Great Americans at the University of New York. At an unveiling ceremony, held on December 1 in the Gould Memorial Library Auditorium of the University of New York, the bronzes were accepted by Dr. C. V. Newsom, president of the University. The principal speakers were Mr. Herbert C. Hoover, former president of the United States, and Dr. D. W. Bronk, president of the U.S. National Academy of Sciences. The bust of Westinghouse, which was given by the American Society of Mechanical Engineers, was sculptured by Edmondo Quattrocchi. The bust of Gibbs, a gift of the American Chemical Society, Yale University, and several individual donors, is by Stanley Martineau.

Site for Expansion of the University of St. Andrews

A statement by the Secretary of State for Scotland, circulated with Hansard for December 17, regarding his decision on the building site for the University of St. Andrews, which was challenged both on procedure and on merits, points out that while the University's evidence at the inquiry was given after the evidence for the objectors, the lines of the University's case had been made clear in advance and its witnesses were intensively cross-examined. The Government's broad acceptance of the Franks report did not mean reopening proceedings already concluded. On merits, Mr. J. Maclay said that the inquiry lasted for ten days, during which all aspects of the matter were fully debated, with a further day devoted to the inspection of sites. It was conducted by a senior and very experienced member of the Scottish Bar as commissioner, wholly independent of the Scottish Office, with the assistance of eminent and independent planning assessors, and his decision was in line with the recommendations in the Commissioner's report. A crucial part is the adequacy of the site for the future scientific needs of the University. The University's view that the Westburn Lane site is adequate and suitable for foreseeable needs of basic scientific teaching and research, that peripheral sites are available if any specialized research necessitated the creation of special buildings at St. Andrews, and that further expansion could still be undertaken at Queen's College, Dundee, was upheld by the Commissioner. Although criticized by the Professor of Physics as shortsighted, this view was supported by the University Grants Committee.

The Commonwealth Trans-Antarctic Expedition

The tractor train of the New Zealand Antarctic expedition led by Sir Edmund Hillary reached the South Pole on the night of January 3. This is the first time that the Pole has been reached overland since the pioneer expeditions of Amundsen and Scott. The expedition, which also includes P. Mulgrew, M. Ellis, J. Bates and D. Wright, reached the American base at the Pole having driven three tractors, two sledges and a caboose 1,200 miles from Scott Base since October 14. The New Zealand expedition, in conjunction with a R.N.Z.A.F. party under Squadron-Leader J. Claydon flying a *Beaver* aircraft, has laid down five depots of food and fuel between Scott Base and Depot 700, about seven degrees of latitude short of the Pole, in support of the United Kingdom trans-Antarctic survey party under Dr. Vivian Fuchs, which proposes to cross the continent from the Weddell Sea to the Ross Sea. At the time of writing, Dr. Fuchs' team, about three hundred miles from the Pole, is encountering hard going from *sastrugi* (ice-ridges) impeding the progress of his tracked vehicles. On January 6 Squadron-Leader J. Lewis, flying an R.A.F. *Otter* single-engine aircraft, traversed the Antarctic continent from the advance British base at South Ice to Scott Base, where Dr. Trevor Hatherington's team of scientists is continuing its programme of observations for the International Geophysical Year.

Soviet and Western Attitudes to Science

The text of a talk entitled "What is the Right Attitude to Science ?" by Dr. K. Mendelssohn, reader in physics in the University of Oxford, broadcast on December 23 on the B.B.C. Third Programme, has recently been published in *The Listener* (January 2, p. 12). Dr. Mendelssohn points out that science and technology, to which the West owes its high standard of living, have been taken so much for granted that they are now accorded second place in the educational system. Now, quite apart from military considerations, the prospect of Russian technological superiority may make it an economic necessity to re-assess the Western position. It is a dogma of Soviet economics that prosperity is based on technological progress, and the rewards to scientists and engineers both in salary and status in the Soviet Union are accordingly high. Even more important is the fact that science in the U.S.S.R. is administered at the highest levels by the Soviet Academy of Sciences and not by politicians or generals. The position is almost the exact opposite in the United States, where the direction of scientific effort is largely in the hands of non-scientists, which not only leads to defective decisions, but also relegates the scientist to a subordinate position. In Britain, on the other hand, while science is mostly directed by scientists, the false dichotomy between science and the humanities has created an almost hostile, or at least defensive, public feeling against science. This, together with early specialization in British schools, has tended to discourage entry into scientific professions. The Russian achievements are largely due to money spent on scientific education and research, even at times when the Soviet Union was passing through economic crises. Dr. Mendelssohn suggests that in Britain more money spent on education could still buy time : time essential for a good general training in both arts and science and for an extra year at a university.

Recent Earthquakes

On December 4 a very great earthquake occurred in Outer Mongolia, with epicentre near latitude 45½° N., longitude 99½° E. The initial time of this shock was 03h. 37m. 45s. G.M.T., and it attained magnitude 7·9 on the Gutenberg–Richter scale. This earthquake was registered on the seismograph at the Royal Observatory, Edinburgh, with maximum ground amplitude of almost 250μ. After-shocks from this and neighbouring epicentres were frequent, especially during the first half of December. Six great aftershocks occurred on December 4, four on December 8 and one each on December 5, 7 and 11, besides numerous smaller ones. All these shocks were registered throughout the world. The area affected macroseismically included the districts of Bayankhongor, Ara Khangai and Ubur Khangai. A wide permanent fissure more than six miles long is said to have appeared in Bayan Tsagan at the time of the earthquake.

On December 13 a smaller earthquake occurred in western Persia with epicentre near latitude 34½° N., longitude 48° E. It had magnitude 7¼, and occurred at 01h. 44m. 59s. G.M.T. It was registered on the seismograph at the Royal Observatory, Edinburgh. The macroseismic effects of this shock were very great in the triangle bounded by Kermanshah, Hamadan and Sanandaj. Murdistan, Assadabad and Kangavar were severely damaged, and Farsinaj was almost destroyed. The earthquake may have caused the deaths of 2,000 people.

The Griffin Gas Chromatography Apparatus

Messrs. Griffin and George, Ltd., have issued a very well-produced pamphlet describing the Mark 2 version of their gas chromatography apparatus. This pamphlet is profusely illustrated with diagrams and photographs, and also contains a short bibliography which will be useful to anyone intending to use gas chromatography for the first time. Typical chromatograms obtained with the Griffin and George equipment are reproduced, and these illustrate the versatility of gas chromatography, showing the analysis of a range of compounds from the C_8–C_{18} fatty acids and their esters, to a series of simple aromatic hydrocarbons. Some indication of the special virtues of a number of different stationary phases is given in a short table.

Zoological Nomenclature

The International Trust for Zoological Nomenclature has arranged for the publication in book form of the first instalment of each of the "Official Lists" of valid zoological names and of the corresponding "Official Indexes" of rejected and invalid names, together with the first instalment of the "Official Lists" of work approved as available for zoological nomenclature and of the "Official Index" of rejected and invalid works. The categories of names covered by these lists and indexes range from specific names to ordinal names, and the total number of entries now to be published is about five thousand. The first of these lists, relating to generic names, was established by the Ninth International Congress of Zoology held at Monaco in 1913, while the most recent were brought into existence by the Fourteenth Congress at Copenhagen in 1953, but owing to the large number of documents now involved it has become difficult for specialists to ascertain what names have so far been registered. This difficulty will be removed by the new publications, each of which will be supplied both with a full alphabetical index and also with alphabetical indexes arranged by major groups. The groups so selected will normally be classes, but in the case of large classes containing well-recognized orders, these supplementary indexes will be on an ordinal basis. All inquiries should be addressed to the International Trust for Zoological Nomenclature at its Publications Office, 41 Queen's Gate, London, S.W.7.

Royal Society and Nuffield Foundation Commonwealth Bursaries

THE following awards under the Royal Society and Nuffield Foundation Commonwealth Bursaries scheme have been announced : Mr. J. Attridge, assistant lecturer in zoology, Birkbeck College, University of London, to enable him to collect and study Karroo vertebrate fossils in Southern Rhodesia during June–October 1958 ; Colonel S. S. Bhatnagar, St. Xavier's College, Bombay, for the study of procedures for the characterization of chemical and pharmacological principles of plants, at Cambridge during April and May 1958 ; Dr. A. J. Buller, senior lecturer in physiology, St. Thomas's Hospital Medical School, London, to enable him to gain practical experience in studying the nervous system by the microelectrode techniques, at Canberra, for about ten months from March 1958 ; Mr. J. Dainty, reader in biophysics, University of Edinburgh, for research on the ionic relations of plant cells and the electrical properties of plant cell membranes, at Sydney, during March–September 1958 ; Dr. W. P. U. Jackson, of the Department of Medicine, University of Cape Town, for the study of specific methods and techniques in endocrine research (prediabetes, plasma insulin activity, calcium and phosphate metabolism) in London, Cambridge and Louvain, during June–August 1958 ; Mr. C. St. J. Lamb, lecturer in electrical engineering, New South Wales University of Technology, to enable him to assist in the development of instrumentation of nuclear reactors used for the production of electrical energy, at Erith, Kent, for a year from January 1958.

University News : Birmingham

THE title of reader in physiology has been conferred on Dr. I. C. Whitfield, senior lecturer in physiology. The following appointments have also recently been made : Dr. R. L. Holmes, to be senior lecturer in anatomy ; Dr. T. R. Lomer, to be lecturer in physics ; Dr. G. Gregory, to be staff tutor in the Institute for Engineering Production ; F. D. Hobbs, to be Paviors lecturer in highway engineering in the Department of Civil Engineering ; and L. Kay, to be lecturer in electrical engineering.

Two new graduate courses have been established in the Faculty of Science : one is a course in the Department of Pure Mathematics leading to a diploma in mathematical statistics, and the other is a course in operational research in the Department of Engineering Production leading to the degree of M.Sc. by examination.

London

THE title of professor of pathology in the University of London has been conferred on Mr. M. H. Ashton in respect of his post at the Institute of Ophthalmology. The title of reader in the University has also been conferred on the following : Dr. A. Armitage (history and philosophy of science) at University College, Dr. Ivy Pinchbeck (social studies) at Bedford College, Dr. C. A. B. Smith (genetical statistics) at University College, and Mr. R. J. Wilkins (civil engineering) at University College.

Malta

IN accordance with the terms of the Royal University of Malta (Constitution) Act of 1957, a Statutory Commission has been formed to "advise the Government on any matter relating to or connected with the University which the Government may refer to them for advice and report, including the expedience of amending or repealing and replacing any Statute for the time being in force or any Regulation made thereunder. No major act of the University which may involve expenditure shall be entered into by the University without the prior approval and advice of the Commissioners who, before giving such approval and advice shall make a report on the matter to the Government and shall consult with the Government on the total amount of funds available. The Commissioners shall also, if so requested by the University, advise the University in the working out of new policies".

Members of the newly appointed Statutory Commission are as follows : Sir Ivor Jennings, Master of Trinity Hall, Cambridge (*chairman*), L. J. F. Brimble, J. S. Fulton and Sir Charles Snow.

Announcements

SIR WILLIAM G. OGG, who has been director of Rothamsted Experimental Station since 1943, will retire on September 30, and the Lawes Agricultural Trust Committee has appointed Mr. F. C. Bawden to succeed him.

PROF. E. LEDERER, of the Institut de Biologie Physico-Chimique, Paris, known for his work on paper chromatography, will be visiting professor in the Department of Chemistry, King's College, University of Durham, Newcastle upon Tyne, for a period of about six weeks, starting on March 4.

THE Institution of the Rubber Industry and the Plastics Institute are holding a joint conference on February 27 at the Institution of Civil Engineers, Great George Street, Westminster, S.W.1. The subject will be "Recent Advances in Polymer Technology". Further information can be obtained from the Secretary, The Plastics Institute, 6 Mandeville Place, London, W.1.

THE Spectroscopic Panel of the Hydrocarbon Research Group of the Institute of Petroleum is organizing a conference on molecular spectroscopy, to be held at the Institution of Electrical Engineers in London during February 27–28. The programme will cover the whole field of spectroscopy. The main topics to be discussed will be nuclear magnetic resonance, technical developments, intermolecular forces and factors affecting intensities of absorption bands. Further information can be obtained from E. Thornton, c/o British Petroleum Co., Ltd., Chertsey Road, Sunbury-on-Thames, Middlesex.

DESIGN OF PHYSICS RESEARCH LABORATORIES

ON November 27, the London and Home Counties Branch of the Institute of Physics held a symposium at the Royal Institution on "The Design of Physics Research Laboratories".

In his introductory remarks, Dr. J. S. Forrest (chairman) recalled that a similar discussion had been held by the Institute of Physics ten years ago (*J. Sci. Instr.*, 25, 157 ; 1948). In the intervening decade, however, there has been intense activity in the building of new laboratories. Moreover, the character of the physics research laboratory is changing ; the conventional laboratory with standard benches equipped with standard services and apparatus is no longer suitable for dealing with many of to-day's problems, which require large machines with the attendant erection and servicing facilities. Accordingly, the time was ripe for a further discussion to put on record the lessons learned during the past ten years and to present the views of architects and research directors responsible for the planning of modern laboratories.

A basic laboratory design which seems to fulfil modern needs, and which was referred to by several speakers, takes the form of a large central area, perhaps 60 ft. wide, with relatively small enclosed laboratories along the sides. The central area must have adequate head-room (more than 20 ft.) and it is therefore possible to provide a number of smaller enclosed laboratories or offices on a gallery over the ground floor laboratories (Fig. 1).

Prof. Basil Spence said he had been concerned with the design of university physics laboratories. Teaching laboratories had to cope with large numbers of students, but the requirements could be defined clearly. Research laboratories, on the other hand, must be extremely flexible in design, as the nature of the work which might be carried out in a few years time was unknown. He had even had to provide for the possibility of increasing the roof height in one project.

Dr. T. Emerson dealt with some problems in the planning of industrial research laboratories. He emphasized the importance of good team-work between the research director, the architect and the builder. The duties and responsibilities of the various parties should be clearly defined at the outset. The requirements for accommodation and services should be co-ordinated and all instructions passed to the architect by one person only, for example, the building supervisor, who might with advantage be the person responsible for the future maintenance of the finished building. The aim should be to construct an adequate building at reasonable cost with plenty of laboratory space to provide future flexibility, sufficient office accommodation, but no unnecessary frills.

A contribution by Charles S. Haines (read by Mr. D. T. R. Dighton) discussed recent trends in the design of American industrial research facilities. In the United States it is becoming common to put the research facilities on a rural site separate from the manufacturing plant. It is important to provide adequate space for future expansion and car parks, and some companies with research organizations of approximately one hundred persons are acquiring sites of more than 200 acres. The design of the buildings must proceed from the inside outwards. To prevent early obsolescence, modular planning is essential, a module being a "three-dimensional repetitive unit of functional space". The satisfactory width of the laboratory module (usually parallel to the exterior wall) may vary from 9 to 12 ft. ; the length may be from 24 to 28 ft. Office modules of 5 ft. × 15 ft. will provide individual and group offices of 10, 15, 20 or 25 ft. × 15 ft. Factory-finished metal partitions are preferred for sub-dividing laboratories, and they should be designed so that room arrangements may be modified without moving the mechanical and electrical services. Air conditioning is desirable, and fume chambers may be required in physics as well as in chemistry laboratories. Many laboratories built in the period from 1949 to 1954 using cheap materials and poor construction are now beginning to deteriorate. Properly planned sound construction using lasting and easily maintained materials will prove to be more economical.

Mr. B. C. Fleming-Williams spoke on services and facilities from the user's point of view. The permanent services—water, gas and waste pipes, electric

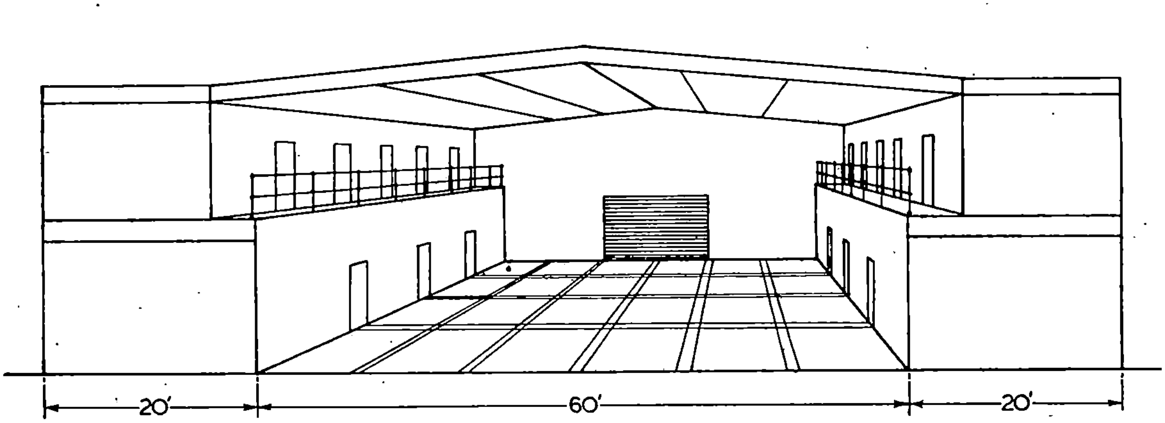

Fig. 1. A basic design for a physics research laboratory

power, lighting, heating and ventilation—should be based on a modular plan. Local supplies may sometimes be preferable to a permanent central installation. For example, direct current can conveniently be supplied from individual power packs instead of from a central battery. Similarly, vacuum requirements can usually be provided by bench pumps, and supplies of various gases from local cylinders. Facilities must be available, however, for the handling and storage of gas cylinders. An adequate and easily accessible duct system should always be installed to enable any central service to be provided at any point if it is found to be desirable in the future.

Mr. J. C. Cornwell discussed buildings and services from the point of view of the laboratory maintenance engineer. He pointed out that maintenance staffs in laboratories are more often concerned with alterations and additions to the buildings and facilities than with simply maintaining the original installation. When the laboratory is designed, provision should be made to facilitate building extensions and alterations to the services. In the choice of partitioning, sound transmission and ease of attachment of shelves are important considerations. Brick and some proprietary types of partitioning are satisfactory, but steel and glass are not. Floor surfaces and their cleaning merit particular attention. Floor ducts should be designed to minimize flooding. Fire protection should receive adequate consideration. Provision must be made for inflammable stores, radioactive sources, gas cylinders and bulky maintenance equipment.

Mr. R. G. Hopkinson spoke on the programme of research on the design of laboratories which is being carried out by the Nuffield Foundation Division for Architectural Studies in collaboration with the Building Research Station. Statistical studies have been made of the bench space and services required by laboratory workers. The work on laboratory lighting was carried out at the Building Research Station. From the determinations of minimum levels of natural and artificial lighting for the efficient performance of laboratory work, a design has been evolved which gives good day-lighting in a single-side lit laboratory. A model was used for assisting in the appraisal of the design (Musgrove, J., and Petherbridge, P., *Architect's J.*, 126, 368; 1957).

In opening the discussion, Mr. D. A. Oliver suggested that two types of laboratory accommodation are generally required—'open space', costing about £2 per sq. ft., and 'better-class' laboratory accommodation costing about £4 10*s*. per sq. ft. The better-class accommodation should be kept free from noise, vibration and dirt; workshops and heavy machines should be in a separate building.

Other matters discussed were the advantages of air conditioning and electric floor warming in research laboratories; a method of providing a wide range of electricity supplies at the benches; and a colour-light staff location system which also functioned as a fire alarm.

In summing up the symposium, Prof. F. A. Vick said that the physicist must make up his own mind as to his requirements, but it is sometimes important that the outside of laboratory buildings should be in keeping with other adjacent buildings. The use of models could be a great help in planning laboratories. Workshops and equipment causing noise and vibration should be kept separate from the research laboratories and offices. The services should be very carefully designed bearing in mind the many points raised in the discussion, and detailed plans of the services properly colour-coded should be handed over with the building. The laboratory furniture should be designed as part of the building. He agreed that it is false economy to save money on the initial cost of the laboratory—taken over a number of years the capital cost of buildings is not usually a very important item in the research laboratory budget.

J. S. Forrest

COLOUR TELEVISION IN UNIVERSITY TEACHING

GUY'S HOSPITAL AND MEDICAL SCHOOL and the British Broadcasting Corporation collaborated to present a series of sixteen demonstrations, lasting more than two hours, which was relayed from Alexandra Palace to Western House, Great Portland Street, London, on the evening of November 19. Marconi's Wireless Telegraph Co., Ltd., provided a colour television projector and a 6 ft. × 4 ft. screen. Although this presentation had been organized for the staff of Guy's Hospital and the Medical School, a large number of representatives from other faculties in the University of London and from medical centres elsewhere were also present.

The purpose was to judge the technical quality of the British system and to consider whether the apparent and potential properties of colour television are sufficiently attractive to warrant a critical trial under practical conditions.

This venture was by no means a stunt. Repeated technical experiments in the research establishment of the Marconi Company at Chelmsford preceded further trials at Alexandra Palace by members of the staff at Guy's representing fourteen different departments. The B.B.C.'s production staff had to evolve new methods and to adapt their equipment to a considerable extent. For example, teaching demonstrations were found to require big close-ups, whereas existing techniques had naturally been designed to satisfy the demands of the theatrical producer. It may be of interest to note that this was the first occasion on which the B.B.C. has transmitted a continuous colour television programme of this length. Meticulous planning was necessary to enable the two cameras to move from one demonstration to the next in less than two minutes. That the presentations followed each other with quite extraordinary precision was the more remarkable as few of the busy physicians and lecturers had been able to attend more than one or two rehearsals. This is a point of importance, as it might be assumed that television techniques in medical teaching will exact undue demands upon the lecturer's time.

The general consensus of opinion was that the quality of definition and colour balance was well above reasonable expectation and most certainly made the use of colour television a practical possibility. It is still to be decided whether this method of communication should be further tested for its effectiveness by a series of critical experiments carried out against the background of university teaching. It was not possible on this occasion to draw any valid conclusions in this respect. The audience consisted of experienced teachers and not students, most of the demonstrations were enacted by senior lecturers, who would normally have been directing such work while actually with their students; and, of course, a large technical staff was available to handle intricate and bulky equipment. Both equipment and methods will have to be simplified drastically to adapt this medium for use in everyday instruction, and there is every expectation that this could be done. However, only practical experience under realistic conditions will show to what extent and how colour television can contribute to understanding and learning.

It may be of value to consider here the essential properties of colour television and how they might possibly be applied. Events and phenomena can be observed at a distance, even when direct vision is not possible. The moving image can be viewed either on large projection screens, or on smaller television receivers in any desired number of places, by large audiences, at the exact time that events are taking place. Fine detail, such as individual hairs on the back of the hand, and large scenes, such as big machinery in a laboratory, can be portrayed with equal ease. High-power microscopic examinations can be made with considerably higher brilliance than is possible with conventional projection microscopes. Preliminary experiments with endoscopes have proved that their use may well become a commonplace, as soon as the associated optical problems have been solved. Live presentation, films, slides and charts can be shown in immediate sequence, and indeed in any desired admixture.

The images from two or more television cameras can be presented in sequence or even side by side. It will thus be possible to correlate separate aspects of the same subject or to contrast similar phenomena by using more than one camera in quite different locations, as, for example, in a laboratory and in a hospital ward.

Perhaps the most important difference from normal visual records such as diagrams, lantern slides and motion picture films is the fact that a live action is shown on the television screen at the exact moment when it happens. Apart from any other considerations, the psychological effect of this upon a student body may prove to be considerable. Whereas a film is rigid in its construction and presentation and cannot easily be arrested, the television demonstration is entirely under the lecturer's control. He can direct the demonstrator through a two-way radio link, he can ask for an alternative presentation of the same subject or for a repetition when he feels that this would be of greater benefit to the students. Mistakes and defects can be rectified immediately, a process which may in fact add to the value of a demonstration, by emphasizing its immediate and local character, and thus imparting to it a liveliness and personal nature often absent from films. Each demonstration can be varied according to the lecturer's wishes and according to the existing knowledge of his students. Participation by the audience can be used where appropriate, for students can both hear and speak to the demonstrator who is with the camera.

Many will maintain that the motion picture film can be used as effectively and more economically. A brief consideration of this contention will expose its fallacy. Even if funds could be raised to establish and maintain sufficient film production units to make films of all the many subjects which can be shown by television, few teachers would have the time required for drafting the initial treatment and for supervising the scripting, rehearsing, shooting and editing of such films. Even if all these films could be made, they would neither fit in with the ideas of other teachers, nor could they possibly be equally effective for different types of audiences. Some 'date' quickly and there are inevitable delays between preparation and exhibition.

Such handicaps do not apply to television. The lecturer discusses with his assistant what he wishes to demonstrate. The camera is placed in position, and the lecturer can direct and control the proceedings as and when he requires them while talking to his students. This demonstration can be as simple or elaborate as he himself may wish.

The use of good colour, a live presentation, the magnification of small detail for large audiences, the juxtaposition of different events or phenomena separated in space, participation by the audience, and complete control by the lecturer can be regarded as the main characteristics which might be exploited. What effect, in terms of understanding and learning, might this have on students? Which type of student will derive the greatest benefit from colour television and at what stage of his learning? Which teaching situations and which disciplines are most likely to benefit from its use? How should it be used to its best advantage? Finally, is the total effect economically worth while? The answers to these questions can only be established satisfactorily when a centre consisting of many different interests and types of student, both undergraduate and postgraduate, is prepared to undertake a full and unbiased investigation of the method. No one will be optimistic enough to imagine that colour television can solve all problems of teaching, nor will any responsible teacher wish to interpose an elaborate electronic device between himself and his class where the normal direct approach can do all he wishes. Nevertheless, experience already shows that television demonstration may permit valuable additions to the content of teaching in many medical subjects, especially by presentation to large audiences of things it is rarely possible to show even to a handful of students. Doubtless, present views and expectations will be modified, and unsuspected potentialities discovered, when it becomes possible to make a full exploration in the working conditions of a medical centre. The results of such an experiment might prove to have far-reaching effects on education, not only in university circles, but also in schools and perhaps even on television broadcasts to the general public.

A colour sound film recording of the demonstration and a booklet published by Marconi's Wireless Telegraph Co. in collaboration with the Illustration Department of Guy's Hospital Medical School are available.

Roger Warwick

AUTOMATION IN THE POST OFFICE

In moving the second reading of the Post Office and Telegraph (Money) Bill in the House of Commons on December 5, the Postmaster-General, Mr. E. Marples, said that during the next two years the Post Office would be spending about £180 million on capital equipment, of which £105 million would be by way of depreciation and ploughed back by the Post Office. Of this sum, more than £167 million would go to telecommunications, £6 million to telegraphs—mostly 'Telex'—and £7 million to postal services. Amplifying the White Paper (see p. 71 of this issue), Mr. Marples, who doubted whether there had been purposeful direction of science and shrewd timing of applied science in the past, explained how in 1958 the saving of £2 million would be achieved in wages as well as at least £10 million-worth of equipment which would have been scrapped under the old system. To secure the maximum use of the £150 million-worth of buried wires, which is increasing at the rate of £11 million a year, the Post Office is trying to bring the automatic line concentrator into operation as fast as possible, and in 1960 it is hoped to have the first all-electronic exchange in operation at Highgate Woods, as a result of the work of the Joint Electronic Research Group, a partnership between the Post Office and private enterprise. By putting in extra repeaters every three miles, it will be possible to make much better use of the existing coaxial cables, either doubling the number of conversations or providing a television channel.

Dealing with the postal services, Mr. Marples said that the procedure in sorting is essentially the same as that used one hundred years ago ; of the total cost of the postal services of £120 million, man-power accounts for 70 per cent. Of that total, sorting accounts for £40 million and delivery for £30 million. The first electronic sorting machine is already in operation at Southampton, and another, the first of a further twenty, should soon be available at Norwich. This development, which is well in advance of the rest of the world, is due to the scientists at Dollis Hill Research Station. It requires for its application a standard envelope, and Mr. Marples emphasized the importance not only of co-operation, particularly with the United States and Canada, in research, but also of public opinion. He said he is starting a scientific survey to find out what the public expect and want from the postal services and how far they are prepared to co-operate, for example, by using a code number for the address. Mentioning the International Committee of Postal Studies, Mr. Marples said that as a result of a visit by the Deputy Postmaster-General of the United States last summer, a team of five Post Office officials has studied mechanization in Canada and in the United States. He had also appointed a committee, with Sir Leonard Sinclair as chairman, "to advise the Postmaster-General on the future place of the inland public telegraph services as part of the communication facilities of the United Kingdom", and he was seeking to encourage co-operation with private industry particularly in telecommunications. Help was being given by the Council for Industrial Design in standardization of telephone exchange equipment and telephone kiosks. Referring to the human problems of automation, after a tribute to the co-operation of the trade unions, Mr. Marples said that he had appointed the general secretary of the Union of Post Office Workers and the chairman of the staff side of the Post Office non-engineering Whitley Committee to the policy committee advising him on mechanization.

In replying to a question in the debate about cable-ships, the Assistant Postmaster-General, Mr. K. Thompson, said that the new two-way Atlantic cable to be laid in a few years, as a result of an agreement with Canada, would be a new plastic-covered cable developed by Post Office engineers and the cable company. British two-way rigid repeaters would provide sixty conversation channels in the single cable, compared with thirty-six in the present double cable.

MEDICAL USES OF IONIZING RADIATIONS

FOLLOWING on the publication of the British and American documents setting out the Hazards to Man of Nuclear Energy, the United Nations Organization set up a Scientific Committee on the Effects of Atomic Radiation. This Committee invited the International Commission on Radiological Protection and the International Commission on Units and Measurements to consider how best to arrive at reliable data for estimating the doses received by different parts of the human body—by individuals, and in the aggregate by large population groups—due to medical use of ionizing radiation. A study group, under the joint chairmanship of Prof. Rolf Sievert and Dr. Lauriston Taylor (chairmen, respectively, of the two International Commissions), decided to spread the work as widely as possible. It was divided among five groups of experts drawn from fourteen countries—Austria, Canada, Columbia, Czechoslovakia, Denmark, France, Germany, Italy, Norway, Sweden, Switzerland, the United Kingdom, the United States of America, and Uruguay.

The genetic hazard is of primary importance, and the data when accumulated will be used for assessing the significant dose per annum to the gonads of any population. A study group of the World Health Organization, which reported earlier this year, considered the possibility of registering systematically doses received by all individuals, but this proposal proved to be unrealistic. There would be too great a margin of error, and too great an expenditure of man-power and of money. There would be difficult legal and psychological consequences. There are, however, certain classes of persons, and certain routine procedures, for which, by a widespread expert sampling survey, sufficiently accurate records can be obtained. The undertaking is by no means a light one. The data available from half a dozen countries, now published in *Physics in Medicine and Biology*, 2, No. 2 (1957), in some eighteen tables, prove to be difficult of collation ; they disclose wide differences of estimated gonad dose. In Denmark and the United Kingdom it is given as about 25 mrad., in Sweden 40 mrad. and in the United States something nearer 100 mrad.

The group recommends an extensive survey, preceded by a pilot preliminary survey. It sets out the desiderata for obtaining uniformly reported information from various countries. These include classifications of age groups, the anatomical type of examination, the radiological type, and the gonad dose per examination for male, female and fœtus. In estimating the dose from the internal use of radionuclides, a factor should be introduced for 'parenthood expectation' for the average patient. It is of interest that, as had been found with other surveys, even the partial investigation so far carried out in Great Britain has already led to a reduction of the gonad dose by adoption of the recommendations included in the last report of the International Commission on Radiological Protection, and the evidence from expert measurement of the actual doses delivered. The means recommended to this end include protective devices for the gonads, a minimum film-focus distance, increased tube-housing protection, permanent filters of at least 2 mm. aluminium equivalent on all diagnostic tubes, the use of higher-voltage techniques, exposure counters on all diagnostic equipment, and the use of image intensifiers.

Since the dose from diagnostic exposure outweighs that from all the other man-made sources, including that from fall-out, it is of great importance that it should be reduced by every means that does not at the same time minimize the great benefits that accrue. Radiotherapeutic dosage is of relatively far less significance.

It is recommended that basic studies should be continued; that in all countries where analysis of film records reveals a dose of more than a few per cent of natural background a detailed analysis should be made; that the sampling programme set out should be followed, after a pre-survey; that the team making the survey should be carefully trained, and make use only of approved dosimeters. Improved practice is confidently anticipated, and as indicated in the tables of Ardran and Crooks, should attain very considerable diminution of dose.

Prof. F. W. Spiers reports on the preliminary survey made in the United Kingdom, which expects to cover at least 5,000 examinations based on some 20,000 exposures, in three classes of hospital, and some clinics. Details of the instrumentation are given, together with forms for recording data so that transfer to punch cards is easy.

ERNEST ROCK CARLING

GIANT MOLECULES

IT seems only yesterday that a professor of physical chemistry told me that a manufacturer had rung him up to ask, "What is this substance 'high polymers' we hear so much about? Can I make tubes of it?" Yet to-day it would be more to the point to ask what cannot be made of it. As for the question what Nature has made of it, answers of ever-increasing wonder and beauty pour out so fast that it is hard work giving them a fraction of the attention that is their due.

Our thoughts just now are much preoccupied, and excusably so, with those problems of atomic energy which betoken such a revolution in what has made up life hitherto that our future has become impossible to assess. All the same, it can be argued that in the long run, if there is going to be a long run, this is a more superficial view of things, because what is scarcely being noticed in the excitement is the quieter but far more pregnant revolution taking place simultaneously in our understanding of the molecular basis of life. Physico-chemically speaking, life is predominantly a question of the activities of chain-molecules in one form or another, and the science of man-made fibres, plastics, rubbers, and related products is an extrapolation therefrom—the lessons of Nature exemplified in a simpler but nevertheless very gratifying piece of 'homework'. The exploration of both these worlds, the old and the new, is now opening up so rapidly and excitingly that a reminder and synthesis such as that recently provided by *Scientific American* (**197**, No. 3; September 1957) in an issue devoted to high-polymer chemistry has a timely helpfulness that makes it doubly welcome. It comprises a set of nine articles by some of the acknowledged authorities in macromolecular studies, and they summarize an enthralling story most effectively.

The first five articles are chiefly about synthetic high polymers, and the other four are about macromolecules in biological structures. Mark starts off with a historical survey entitled "Giant Molecules", followed by Debye on "How Giant Molecules are Measured", Natta on "How Giant Molecules are Made", Tobolsky on "The Mechanical Properties of Polymers", and Oster on "Polyethylene"—the simplest chain-molecule of its kind, but extraordinarily versatile and fast becoming the commonest. Preston writes next on "Cellulose", Doty on "Proteins", Crick on "Nucleic Acids", and finally Schmitt on "Giant Molecules in Cells and Tissues". The level of presentation is uneven, with the elementary concept often explained at lengths which some readers might prefer devoted to more advanced parts, which are as a result rather glossed over. Some non-uniformity is almost unavoidable in articles of this sort, semi-popular and aimed at informing and interesting as wide a range of reader as possible. Taken together, these articles must certainly succeed in doing that: there is something for everybody, from the beginner to the specialist. The illustrations are particularly fine for teaching purposes, and there is a very useful bibliography.

Among the biological contributions which I, personally, found most enjoyable, was that by Doty, in which he tells of recent progress, by measurements of light scattering and optical rotation, in detecting the states of folding of synthetic polypeptides and proteins in solution. The former can change over, reversibly, from right-handed α-helices to randomly coiled chains, depending on *p*H and other conditions, and the transition is marked also by such characteristic changes in the optical rotation and rotatory dispersion that it is natural and seems well justified to apply the criteria to the globular proteins. The results indicate (as had already been suggested from X-ray and related studies) that such globular protein molecules as have so far been tested do indeed include α-helices in their make-up, to extents varying from 15 per cent in ribonuclease to 85 per cent in tropomyosin; and what is more, these proportions can be varied reversibly, and when the protein is an enzyme, activity goes up and down correspondingly. By implication, the same sort of adaptability of the intramolecular mixture of α-helical and randomly-coiled could account for the versatility of the γ-globulins and the formation of antibodies.

The main theme of Natta's article is the astonishing advances in the controlled building of high polymers that have been made within only the past few years by means of complex ionic catalysts, following Ziegler's production, for example, of unbranched polyethylene at atmospheric pressure and temperatures not much above 30° C. Vinyl polymers now run into molecular weights of millions, with their side-groups arranged at will in a so-called 'atactic', 'isotactic' or 'syndiotactic' sequence according as they occur at random on either side, all on the same side, or regularly distributed from side to side. Truly, as Natta says, "we can hardly begin to conceive how profoundly this new chemistry will affect man's life".

All this though, impressive as it is, is still child's play compared with the kind of thing discussed by Crick in his article on the nucleic acids. Deoxyribonucleic acid and ribonucleic acid have lately come to be recognized as the 'master race' of biological high polymers, in that apparently they alone can both transmit messages of heredity and afterwards dominate the business of protein synthesis. Recent discoveries in bacterial genetics are more than fascinating; they are also perhaps rather disturbing, particularly in the light of the changes reported (J. Benoit, P. Leroy, R. Vendrely and C. Vendrely) to have been induced in White Pekin ducks simply by injecting into their peritoneal cavities soon after birth samples of deoxyribonucleic acid prepared from Khaki Campbell ducks. We can dimly see approaching a day when not merely bacteria but also higher animals and even human beings may have their transmissible characters moulded synthetically—a most alarming thought in some ways.

More dimly still, but now not nearly so as it appeared only a short while ago, a day can be envisaged when we may be able, in a process analogous with infection by a bacteriophage, or with any fertilization, to add a synthetic polynucleotide to a collection of synthetic substrates and thereby set going a little hive of 'synthetic life'.

There is something seriously wrong with dreams such as this, of course. Systems of proteins and nucleic acids and accessory molecules with nothing else can scarcely keep on thinking and asking questions about themselves and experimenting on themselves until they have at last succeeded in making themselves. Reason apart, the halt will surely be called by an ultimate indeterminacy principle which says that it is impossible to place the required components in their correct places all at the same time.

W. T. Astbury

EDUCATION FOR A TECHNOLOGICAL AGE

DELIVERING the ninth Hinchley Memorial Lecture to the Institution of Chemical Engineers on November 5, under the title "An Education for Our Times", Dr. R. P. Linstead, rector of the Imperial College of Science and Technology, London, said that the proportion of scientifically qualified men to the total employed in British industry as a whole is 0·8 per cent. The proportion varies, however, in the principal scientific industries from 10·9 per cent in nuclear power, 5·2 per cent in oil refining, to 2·7 per cent in chemical industry and 1·9 per cent in the aircraft industry. This vocational demand is likely to increase, but Dr. Linstead insisted first that science is an intellectual discipline of the first rank in its own right, and secondly that when the current very large requirement for scientists and engineers has been met by the necessary adjustments in our pattern of education, man will still have to meet his ultimate problems of virtue, civilized behaviour and the wise conduct of affairs. He argued that the study of pure and applied science provides an education peculiarly suitable to our times, and, limiting himself essentially to the higher education of boys from fifteen years upwards at school and university during the next decade, explored four questions.

The answer to the first, whether we have enough qualified engineers and scientists, is no, and Dr. Linstead said that in the next few years an increasing proportion of science specialists in the schools should be diverted from science to engineering when they reach the universities, and university departments of technology must be provided with the necessary facilities. In considering the second question, when their education should become specialized, he suggested that specialization in science and mathematics should not be pushed to the extent that a boy loses touch with the world of human studies and values, and he would like to see more flexibility in the general educational pattern, with some lightening of the requirements in factual scientific knowledge and, above all, search for intelligence. In discussing the third question, namely, whether the first-degree course should be longer, Dr. Linstead pointed out that this would involve additional capital expenditure of £15 million to £30 million, a large increase in recurrent expenditure and a hiatus in output for one year of at least 7,000 men. Rejecting this as impracticable, he urged that a real contribution could be made at the university-level by postgraduate instruction in the new types of scientific technology, where there is a real intellectual discipline to be mastered and not just a technique to be acquired.

In answer to his last question, whether scientists and engineers should be taught non-scientific subjects at the university, Dr. Linstead argued that any good system of education would provide a good product out of good material, against a good social background. In considering how far assistance can be given to students of science and technology to acquire a broader education and the attributes of leadership during their university career, Dr. Linstead suggested that, in general, compulsory and examinable non-scientific subjects should not be introduced into a three-year first-degree course. The college or university should, however, make a continuous and organized effort to provide facilities whereby a student can broaden his outlook, interests and experiences. In addition, certain types of non-scientific studies arise directly and, as it were, functionally out of a man's vocational interests and should very properly be studied in an organized way as part of them or side by side with them; for example, languages, some aspects of economics, and the history of science and technology. Finally, Dr. Linstead urged that the benefits of organized and compulsory classes in cultural subjects are limited, and in the last resort it is more important for a technological university to provide the facilities for a full life in human surroundings.

MANAGEMENT, GROUP CONFLICT AND THE SCIENCES

A PENETRATING analysis of management attitudes towards group conflicts in industry has been made by the Earl of Halsbury, managing director of the National Research Development Corporation (*Impact of Science on Society*, 8, No. 3). Management is an act which occurs in opposition to some form of resistance, and to treat it as a problem in communications is inadequate. No mere verbal exposition of what a man does not want to do will make him want to do it. The fact that someone else wants it will not make him want it either. In some way the individual has to identify his wishes and hopes with those of others, with whose wishes and hopes his own were originally in conflict.

According to text-book expositions, change occurs because 'loyalty to the firm' binds management and workers together, and what is in the interest of the whole will ultimately seem to be in each individual's own interest, and will thus produce co-operation.

Unfortunately, great numbers of the human race are psychologically immune to any such approach.

Using an approach from social anthropology, Halsbury shows that within any one culture pattern a mosaic of variant sub-patterns can be seen, each with its characteristic ideology. The tyranny of words leads to over-simplification. People talk of 'the industrialist' and 'the trade-unionist' because grammar and syntax do not permit individuals to talk of them at all unless it is done in this way. To refer to 'the industrialist' or 'the trade-unionist' implies a homogeneity that does not exist. Some North American Indian language is needed which would enable one to treat as single nouns such complexes as the following: 'Church-going-factory-manager-with-strong-sense-of-public-service'; 'Free-trade-golf-playing-managing-director-believing-keep-out-of-my-way; 'Union-chairman-christian-naming-employers-confederation-operating-ancient-agreement-never-broken'; 'Vicariously-bitter-shop-steward-with-chip-on-shoulder'.

Treatises on managerial techniques which avoid reference to basic situations merely skim the surface of the subject. If social anthropology and industrial psychology are to be the nuclei of some future intellectual discipline which will transform and adjust human relations in accordance with human needs, then present indifference to the realities of 'intractable situations' must give way to an active interest in what ought to be the heart of the subject.

Tractable situations are, after all, tractable. If one knows what to do and has the will to do it, then an undesirable state of affairs will remedy itself in due course. A few pioneers will take the lead, and the rest of the community, giving time for imitation, will follow suit. In this way, factory welfare and managerial interest in workers' recreational and social life have spread throughout the industrial community. These are the mechanical contrivances of management. What is of paramount interest is why they are frequently ineffective. Why is one local ideology apparently unable or unwilling to copy what is manifestly successful elsewhere ?

Group negotiations are, in practice, never carried on between groups. They take place between negotiators representing them. These negotiators occupy points on a spectrum stretching from the pure amateur at one end to the pure professional at the other. Their attitudes towards their status as negotiators must be a factor of some importance in determining the way negotiations proceed. They may or may not identify themselves with the group that they represent; they may or may not share its ideology. The professional will be less likely than the amateur to concern himself with group ideology and more likely to represent the group's views dispassionately on a consultant-client basis. The professional will be more anxious to calculate precisely what his client can hope to obtain, and then seek to obtain it.

An important feature of the professional's attitude is reluctance to give a point away on behalf of his client without instructions. If the client is a collective, a group, reference back for instructions is clumsy to the point of virtual impossibility, and professional reluctance to give way even on a trivial point may cause negotiations to be drawn out over a long period. The protraction of negotiations in this way may itself contribute to modifying group attitudes.

In a well-reasoned article, Halsbury shows that it is for sociologists to become the influential minority capable of switching attitudes over from one configuration to another. The social sciences are not only the youngest of the sciences; they also lack their popularizers. Of all the sciences, sociology should exercise the most powerful impact on society, just as introspection exercises the most powerful influence on minds.

DISTRIBUTION OF GLOBULIN PERMEABILITY FACTOR AND ITS INHIBITOR IN THE TISSUE FLUID AND LYMPH OF THE GUINEA PIG

By PROF. A. A. MILES, C.B.E., and D. L. WILHELM
Lister Institute of Preventive Medicine, London, S.W.1

THE substances—like histamine, leukotaxine, plasmin and 5-hydroxytryptamine—variously held to be the initiators of the increased permeability of small blood vessels in inflammation are presumably released in the extravascular tissues. Their release in the blood itself is unlikely, because they would be removed too rapidly by the blood stream to have an effect confined to the inflamed region. The demonstration of a potent globulin permeability factor present in an inactive form (pro-permeability factor) in the serum of the guinea pig[1,2], rabbit[2–4], rat[2,3,5], man[2,6,7], and cat, dog, horse, ox and mouse (unpublished observations), while adding another candidate for the role of a natural endogenous mediator in the inflammatory response to injury, poses the problem of how, without the intervention of other permeability factors, the inactive form in the blood reaches the extravascular tissues for activation. We now have good evidence that in the guinea pig not only pro-permeability factor, but also the serum globulin inhibitor of permeability factor, are normally present in the tissue fluids.

In order to sample the tissue fluids without damaging tissue cells and thereby releasing intracellular material, we devised a method of intercellular perfusion; taking advantage of the fact that in the skin of the guinea pig's trunk, intracutaneously injected saline spreads mainly in the plane of the skin, without leaking through the epidermis or the fascia deep to the panniculus carnosus. The saline, with the materials it has gathered in its intercellular passage, can be harvested at a cut edge of skin at any required distance from the point of injection. The apparatus, designed to limit the perfusion to one direction only, is shown 'dissected' in Fig. 1. A piece of freshly excised skin, including all the layers down to the loose subcutaneous tissue immediately below the panniculus carnosus, is firmly clamped between

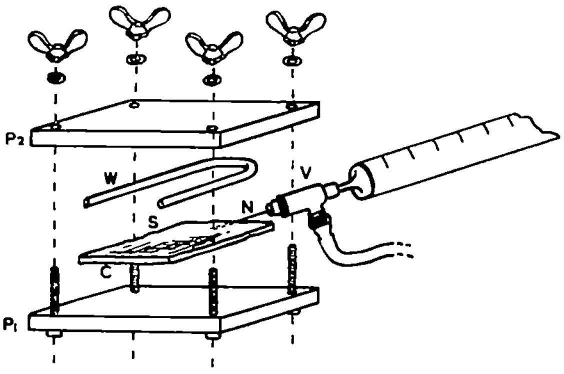

Fig. 1

two 'Perspex' plates, $P1$ and $P2$, which are kept 2–3 mm. apart by an elongated U-shaped piece of rubber-covered wire W. A strip of skin S, 10 mm. × 35 mm., is thus isolated and sealed except at one narrow cut edge C at the open end of the U-piece. At the other end of the strip a No. 26 gauge needle N, for the injection of physiological saline or Locke's solution, is inserted with its tip immediately below the dermis, and the skin clamped in position with its subcutaneous surface in contact with the U-piece. The U-piece is slightly notched at its mid-point to accommodate the thickness of the needle. The needle is mounted on a B–D double valve V No. 470V, which is used as a three-way tap, and to which is connected a tuberculin-type 1-ml. syringe and a reservoir of perfusion fluid.

Under syringe pressures of 3–4 atmospheres the saline flows along the skin strip to the open end of the U-piece, where it is sampled. Perfusion is greatly facilitated by adding 40 units of hyaluronidase to the first 0·5 ml. of perfusion fluid. In this concentration, the enzyme has no permeability factor activity and does not alter such activities in the perfusate. Its use also ensures that the tissue cells are forced apart during the injection with the minimum of trauma. Permeability factor activity is measured in terms of the diameter of the area of exudation of circulating pontamine blue (mean lesion diameter, Fig. 2) induced at the site of intracutaneous injection in the trunk of the guinea pig[8].

Locke's solution perfusates of fresh skin, 10 mm. × 35 mm., tested 30 min. after harvesting, yield a permeability factor most of which appears in the first 3 ml., which contains about 90 effective blueing doses[1] (plasma contains[2] up to 20,000 such doses per ml.). The contribution of permeability factor from any intravascular plasma in the skin strip is negligible, because the perfusates are similar whether the skin is taken from animals exsanguinated after stunning, or from an area of skin of the flank previously perfused *via* the axillary artery with gelatin–Locke's solution until free of any visible traces of blood. Like the serum permeability factor, the intercellular permeability factor is inhibited by soya bean trypsin inhibitor and by the fraction of guinea pig serum containing inhibitor of permeability factor, but not by the antihistaminic drug, mepyramine maleate.

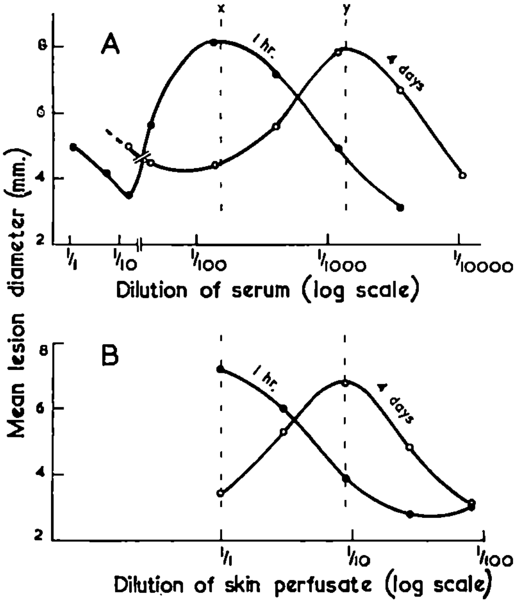

Fig. 2

That it is obtained as permeability factor, and not in its inactive form, is to be expected, since the small quantity of intercellular fluid obtainable from 0·8 gm. of skin is diluted in 3 ml. Locke's solution; and it is a characteristic of the pro-permeability factor in undiluted serum that it is activated by simple dilution[1]. After ½–1 hr. at 22° C., serum permeability factor is activated in the dilution zone 1/50–1/1,000; in the zone 1/1–1/30, any activated permeability factor has been inhibited by the native inhibitor present; but when dilutions are held for four days at 4° C., zones of activation and inactivation shift into ten-fold higher dilutions (Fig. 2*A*). A readily elicited property, therefore, of the system is that a given dilution x first contains permeability factor and later loses it, whereas a higher dilution y is at first inactive and later acquires permeability factor activity. This property is displayed by skin perfusates (Fig. 2*B*)—indicating that the intercellular fluid contains inhibitor, and suggesting that the permeability factor has been activated from its inactive precursor.

The probable existence of intercellular pro-permeability factor is established by the examination of normal lymph. Lymph was harvested in healthy animals under urethane anæsthesia from the cervical ducts lying on each side of the trachea. Both native lymph after removal of the clot, and slightly heparinized lymph, have little permeability factor activity when tested intracutaneously in the undiluted state; but on dilution activation occurs within 30 min. at 22° C. in the zone 1/5 to 1/100. Moreover, on holding the dilutions at 4° C. for 1–2 days, the zone of activation shifts into higher dilutions, as it does in dilutions of serum and of intercellular perfusates (Fig. 2). The permeability factor in lymph is inhibited by soya bean trypsin inhibitor and by guinea pig serum permeability factor inhibitor, but not by mepyramine. Since the lymph could be harvested with rigid precautions against contamination with shed blood, the results, unlike those with the skin strip, are not open to the criticism that traces of intravascular plasma permeability factor may have been present in the perfusates.

It appears, therefore, that the proteins constituting the pro-permeability factor/inhibitor system of the blood pass normally into the intercellular fluid and rejoin the circulation *via* the lymph. There are thus no topographical obstacles to an immediate, local, extravascular activation of permeability factor in the appropriate pathological circumstances; and there is no need to postulate additional mechanisms whereby serum pro-permeability factor is brought into the tissues at the time of injury. As we have noted before[2], the ready activation of serum permeability factor by simple dilution suggests that it is activated *in vivo* by relatively mild means; but the presence of the pro-factor in both lymph and tissue fluids is inconsistent with the notion that permeability factor is activated as the result of actual dilution of exuded plasma proteins in the tissue fluids.

SPECIES-SPECIFIC DIFFERENCES IN FREE AMINO-ACIDS AND PEPTIDES IN SEA-URCHIN EGGS AND EMBRYOS (PURE SPECIES AND HYBRIDS)

By Dr. P. S. CHEN
University of Zurich
AND
Prof. F. BALTZER
University of Berne

STUDIES of amino-acid metabolism in sea-urchin development have been carried out on *Strongylocentrotus purpuratus*[1,2] and *Paracentrotus lividus*[3,4]. In both species it was found that free glycine is present in large quantities in the developing eggs, and that distinct quantitative changes of the free amino-acids occur in the course of morphogenesis. Recently, in connexion with experiments devoted to studies of protein metabolism in sea-urchin hybrids, we used the technique of paper partition chromatography to study the amino-acids at various developmental stages of *Paracentrotus lividus*, *Arbacia lixula* and *Sphaerechinus granularis*. These species belong to three different families and, according to our chromatographic results, differ from each other in their patterns of free ninhydrin-positive substances. This is a preliminary report on such species-specific differences detected on our two-dimensional chromatograms and on the corresponding chromatographic patterns in the hybrids *Paracentrotus* ♀ × *Arbacia* ♂ and *Sphaerechinus* ♀ × *Paracentrotus* ♂.

Materials of all three sea-urchin species were collected from the Bay of Naples in March and April, 1957. Only fresh specimens were used for fertilization. The fertilized eggs were kept at 18° C. until the desired stages of development were reached. The latest stage examined in the present study was the pluteus shortly before feeding. In addition, the amino-acid content of the unfertilized eggs was also determined. These eggs were usually obtained from that female which had been used for the fertilization.

The procedures of preparing the amino-acid extracts are as follow: a measured volume of culture suspension containing on the average 10,000 eggs was first concentrated by centrifugation. The sedimented eggs, after removing the sea-water very carefully, were homogenized in a microhomogenizer and extracted in 80 per cent methanol. After centrifuging the sample again, the supernatant was applied with a fine pipette to a Whatman No. 1 filter paper (28 cm. × 46 cm.). A second extraction was carried out, and the supernatant again transferred to the sheet. The paper was first run in 70 per cent *n*-propanol (ascending) and then in water-saturated phenol (descending). After the phenol run the spots were made visible by spraying the sheet with 0·5 per cent ninhydrin in 96 per cent ethanol, followed by heating at 90° C. for 15–20 min.

Three typical two-dimensional chromatograms of the sea-urchin species investigated are reproduced in Fig. 1. In *P. lividus* the following free amino-acids, amides and peptides have been found in eggs and embryos of different stages: aspartic acid, glutamic acid, serine, glycine, threonine, tyrosine, α-alanine, β-alanine, glutamine, cystine, ornithine, lysine, asparagine, arginine, histidine, proline, valine (and/or methionine), leucine (and/or *iso*leucine) and five peptides (Fig. 1, *A* and Table 1). In accordance with the results reported by earlier authors[1,2,4], glycine was found to occur in abundant quantities with α-alanine next to it. The concentration of other free amino-acids is very low. Among the peptides, spot No. 20 has been identified as glutathione by adding pure substance to the extract. Spot No. 21 gives a brown, and spot No. 22 a green-blue, colour with ninhydrin. Since both spots disappear from the extract after acid hydrolysis, they are probably peptides, too. Because of their low concentrations we have not been able to carry out further analyses on these two substances.

The free amino-acid picture of *A. lixula* (Fig. 1, *B*) looks quite different from that of *P. lividus*. First, the concentration of glycine is by no means higher than that of the other amino-acids detectable in the free form. Second, spots No. 21 and No. 22, which showed a constant occurrence in the *Paracentrotus*-extract, have never been traced in this species. Third, the *Arbacia* chromatogram is characterized by the appearance of a new spot of particularly high concentration (spot No. 17 in Fig. 1, *B*). Considering that this substance reacts readily with ninhydrin and is resistant to acid hydrolysis, it is assumed to be an amino-acid. With the solvents used in the present study its R_F values (0·48 in 70 per cent *n*-propanol, 0·74 in water-saturated phenol) are very close to those of methionine sulphoxide, and β- and γ-aminobutyric acid. It is obviously not methionine sulphoxide, because no methionine sulphone was formed by oxidation with hydrogen peroxide. It behaves very similarly to the substance 'fast-aminobutyric acid' described by Dent in plant extracts and in blood and urine[5]. Our investigations to ascertain the chemical nature of this spot are still in progress.

* Those substances, which are listed in the present table and not shown on chromatograms in Fig. 1, give very faint spots, and have been observed only occasionally.

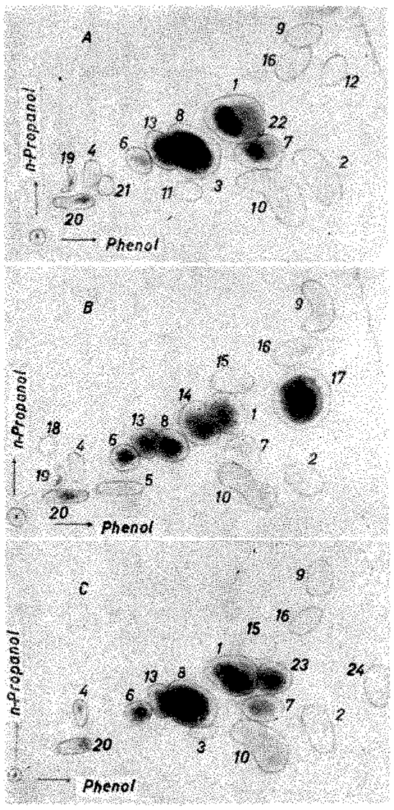

Fig. 1. Free ninhydrin-positive substances in methanol extracts of sea-urchin eggs and embryos. The chromatograms are not from corresponding stages, but the amino-acid pattern of each species remains largely unchanged during development. *A*, *Paracentrotus lividus* (10, 178 unfertilized eggs); *B*, *Arbacia lixula* (20, 772 early plutei); *C*, *Sphaerechinus granularis* (6,266 unfertilized eggs). 1, α-Alanine; 2, Arginine; 3, Asparagine; 4, Aspartic acid; 5, Cystine; 6, Glutamic acid; 7, Glutamine; 8, Glycine; 9, Leucine (and/or *iso*leucine); 10, Lysine; 11, Ornithine; 12, Proline; 13, Serine; 14, Threonine; 15, Tyrosine; 16, Valine (and/or methionine); 17, 'Fast-aminobutyric acid'; 18–23, Peptides; 24, Unknown spot

The chromatogram of *S. granularis* is similar to that of *P. lividus* in so far as glycine occurs in enormous quantities, and spot No. 17, which is characteristic for *A. lixula*, was also not recorded in this species. However, a closer examination of the chromatogram revealed another new spot which is apparently specific for *Sphaerechinus*, and has been found in extracts in both unfertilized eggs and developmental stages ranging from blastula to pluteus (spot No. 23 in Fig. 1, *C*). The R_F values (0·41 in 70 per cent *n*-propanol and 0·64 in water-satured phenol) suggest this substance to be β-alanine. Its ninhydrin colour is, however, not blue, but purple. It cannot be citrulline, because no yellow spot was formed by spraying the paper with a 1 per cent solution of *p*-dimethylaminobenzaldehyde. The fact that the unknown compound disappeared from the extract upon hydrolysis indicates that it is a peptide. This point was confirmed by eluting the material from the area and subjecting the eluate alone to hydrolysis. The hydrolysate was shown to contain chiefly α-alanine with a moderate amount of glutamic acid and a trace of aspartic acid. Another substance (spot No. 24 in Fig. 1, *C*, and unknown in Table 1) has been traced also only in *S. granularis*. It gives a very faint spot, and was not investigated further by us.

In all three types of eggs the patterns of free amino-acids, in spite of their quantitative changes, remain largely constant during development. (Results concerning the quantitative changes of free amino-acids and peptides during the development of both parental species and the hybrids will be published elsewhere.) Thus, the specific differences described above can be noted in every stage of development. Table 1 is a summary of all free ninhydrin-positive substances, the existence of which has been so far established in the three sea-urchin species examined by us.

Further efforts were made to analyse the amino-acid composition of the proteins denatured during the methanol extraction. After pipetting out the supernatant for chromatographic separation, the protein precipitates were suspended in 6*N*-hydrochloric acid for hydrolysis at 110° C. for about 12 hr. In contrast to the findings quoted above, the protein hydrolysates of all three sea-urchin species are strikingly similar in their amino-acid constituents. These consist of aspartic acid, glutamic acid, serine, glycine, threonine, α-alanine, tyrosine, lysine, arginine, histidine, proline, valine (and/or methionine) and leucine (and/or *iso*leucine). It is of particular interest that glycine, which was found to be present in unusually large quantities in the methanol extracts of both *Paracentrotus* and *Sphaerechinus*, shows a relatively low concentration in their protein hydrolysates. In *Arbacia* the substance corresponding to spot No. 17 has never been located on the hydrolysate chromatogram. In other words, the species-specific differences described for the free amino-acids are not reflected in the amino-acid composition of the proteins. This may indicate that differences of specific proteins in the sea-urchin egg, as demonstrated by serological studies[6], probably lie on the structural level.

The chromatographic patterns of the corresponding substances in the two hybrids studied show an entirely maternal character (compare Table 1). It may be added that these hybrids are very different in their developmental behaviour. The development of *Paracentrotus* ♀ × *Arbacia* ♂ is normal and maternal until the beginning of gastrulation (like many inter-specific hybrids). Then the development stops and the inhibited gastrulæ die. On the contrary, *Sphaerechinus* ♀ × *Paracentrotus* ♂ develops normally to the pluteus stage, which shows, as it is well known, maternal and paternal character in the skeleton[8]. In spite of this intermediate behaviour the chromatographic pattern is completely maternal.

The relationship between protein metabolism and morphogenetic development has been demonstrated to be a complicated one[7]. The fact that the amino-acids, in spite of their high concentration in the free, non-protein fraction, are either not detectable or occur only in unproportionally minute quantities in the proteins, suggests that they serve some special purposes rather than being merely building stones of proteins. In the *S. purpuratus* egg there is evidence that certain amino-acids play a part in the energy metabolism, while others play a part in the osmoregulation[2]. It is uncertain if this conclusion also holds true for the other sea-urchin species and for the hybrids. The function of the new spots found in *Arbacia* and *Sphaerechinus* reported here for the first time is entirely unknown. We shall now try to ascertain their metabolic roles. Given a more complete knowledge about these substances it would be possible to find out to what extent such specific differences in the amino-acid patterns are responsible for the developmental potencies of the hybrid embryos[8].

Our work was made possible by a grant from the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung. We wish to thank the authorities at the Zoological Station of Naples for their most generous help. Thanks are also due to Prof. E. Hadorn for encouragement and valuable discussion.

PHOTOPERIOD, AUXIN AND SEX BALANCE IN A LONG-DAY PLANT

By PROF. J. HESLOP-HARRISON and Y. HESLOP-HARRISON
Department of Botany, The Queen's University, Belfast

REPORTS on the effects of photoperiod on sex expression in diclinous flowering plants have mostly suggested that photoperiodic régimes which promote early or abundant flowering tend, initially at least, to enhance femaleness, the response being apparent in the production of a greater proportion of pistillate flowers, or in intersexuality in staminate ones[1]. Comparable effects can be induced by treatment with synthetic auxins in various monoecious Cucurbitaceae[2-5] and in the dioecious *Cannabis sativa*[6]. The present article reports corresponding results in a long-day plant with monoclinous flowers, *Silene pendula* L.

Seeds of two cultivars, *ruberrima* and *compacta* (obtained from Messrs. Thompson and Morgan, of Ipswich), were germinated in a mixture of sand and peat, and the seedlings transplanted at a height of 4–5 cm. to individual pots, where they received on alternate days a 15-ml. ration of a balanced nutrient solution containing about 200 p.p.m. nitrogen. The plants were grown throughout in a greenhouse with night temperature regulated between 20° and 22° C. Short-day treatment was given by enclosing the plants in ventilated dark cabinets from 5 p.m. until 9 a.m. daily. Plants receiving long days were exposed to natural daylight with supplementary illumination at 300–400 ft.-candles from a mercury vapour source to give a total light period of 21–22 hr.

Matched groups of eighteen plants of var. *ruberrima* and ten of var. *compacta* were grown to an age of 40 days in long days, and half of each group then transferred to short days. Short-day treatment was continued for 50 days with the plants of var. *compacta*. Those of var. *ruberrima* had a break of 4 long days after 24 short days, during a period when the dark cabinet was required for another experiment; they were then returned to short days for a further 22 days. This long-day break appeared to have no effect on the development of the plants of var. *ruberrima*, and at the end of the 50-day period, all plants of both varieties which had received short days were rosettes with a condensed main axis and no extended lateral branches. At this time, the series of both varieties which had received long days throughout had developed 6–9 first-order laterals and were differentiating flower buds. Following restoration to long days after the 50-day period, the short-day series of both varieties rapidly produced lateral branches, and flowering began in all within three weeks. The final records of flowering behaviour were taken in all series 130 days from the beginning of germination.

Estimates of male fertility were based upon samples of 100 randomly collected flowers from each plant. In male-sterile flowers, development of the androecium may be arrested at any stage from the emergence of the primordia to the end of micro-sporogenesis. However, since the formation of fertile pollen is marked by a change of the anther colour from yellow to purple, male sterility may be recognized without resort to microscopy even when its onset is delayed until the completion of meiosis. Every stamen in

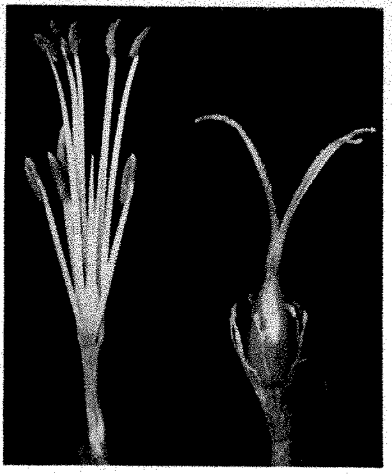

Fig. 1. (*a*) Normal flower (calyx and corolla removed) from a plant of *Silene pendula* var. *compacta* flowering in long days (21–22 hr. light) after an interlude of 50 short days (8 hr. light). Anthers of the first flush are shedding pollen; those of the second group have not yet dehisced, and the styles have not yet emerged from the corolla tube. (× *c.* 3). (*b*) Male-sterile flower at a corresponding stage from a plant of *S pendula* var. *compacta* grown throughout life in long days,. showing the contabescent anthers and greatly enlarged gynœcium. (× *c.* 3)

each flower of the sample was examined, so that the proportion of sterile stamens in a total of 1,000 was recorded. The results are given in Table 1. Whereas in the plants which received a period of exposure to short days male fertility was consistently high, all the plants grown throughout in long days were male sterile to a greater or lesser extent. In none of the totally male-sterile flowers were the anthers exserted beyond the limb of the corolla, and the ovary was usually considerably more swollen than in the perfect flowers of plants of the short-day series at the time of anthesis, an effect reflected in the enlarged calyx of the young flowers (Figs. 1 *a* and *b*). Male sterility was associated also with a marked diminution of corolla size; thus the mean maximum diameter of the limb of the corolla in a sample of forty flowers from a short-day plant of var. *compacta* was 20·06 ± 0·26 mm., and in the same number of totally male-sterile flowers from a long-day plant of the same variety 12·99 ± 0·22 mm. The fully male-fertile flowers produced on the long-day plants were mostly the distal ones in each partial or complete dichasium. Like those of the short-day plants (Fig. 1*a*) they were protandrous, the anthers emerging in two flushes, the five of the outer antepetalous whorl followed by those of the inner whorl, 50–60 hr. before the exsertion of the styles.

In preliminary experiments with auxin, general applications of α-naphthaleneacetic acid in aqueous solution were given to plants under various photoperiodic régimes. Though clear indications were obtained of the induction of male sterility under conditions in which control plants showed normal fertility, the concentration of α-naphthaleneacetic acid producing this effect was sufficient to cause high mortality among treated plants and severely to depress the general vigour of survivors. With plants showing general debility, it did not seem justified to conclude that loss of male fertility was a specific auxin effect. In further experiments a specific effect was demonstrated by limiting treatment to particular branches of vigorously growing plants during the period of flower differentiation.

Table 1. Mean Numbers of Sterile Anthers per Sample of 100 Flowers per Plant in Two Varieties of *Silene pendula* under Two Photoperiodic Régimes

Long-day and short-day treatments as in text

	Long-day	Short-day
Var. *ruberrima* (9 plants per series)	522·3 ± 56·0	6·67 ± 2·14
Var. *compacta* (5 plants per series)	427·8 ± 95·8	13·00 ± 1·85

In an experiment with var. *compacta*, two vigorous 90-day old plants were transferred to long days after exposure to fifty short days. Lateral shoots began to extend after ten long days, and at this stage, at the onset of flower differentiation, three pairs of basal leaves of five shoots in one sector of each plant were treated with lanolin paste containing α-naphthalene-acetic acid at 0·5 per cent, each leaf receiving about 0·1 gm. of the paste. The flowering behaviour of these shoots was followed during the subsequent four weeks, and the over-all male fertility compared with that of other floriferous untreated branches of the same plants. The striking effect of α-naphthalene-acetic acid in depressing male fertility is apparent from Table 2.

Table 2. Effect of α-Naphthaleneacetic Acid on Male Fertility in *Silene pendula* var. *compacta*

Sterility of anthers in all flowers formed on five treated laterals of each plant compared with that in a sample of 100 flowers from untreated branches of the same plant. Treatment details as in text

Plant No.	Untreated laterals per cent sterile anthers (100 flowers)	Treated laterals	
		No. of flowers	per cent sterile anthers
*SC*7	1·2	27	84·8
*SC*15	1·1	21	75·7

In a similar experiment with var. *ruberrima*, treatment was restricted to one outgrowing lateral, the auxin paste being applied to the lower surfaces of successive pairs of leaves as they opened. Flowering was retarded and somewhat reduced by this treatment, but again an unequivocal effect upon male fertility was apparent, as may be seen from the records of the individual plants in Table 3.

A feature of auxin-induced male sterile flowers of both varieties was the remarkable precocity of development shown by the gynœcium. Frequently the styles were exserted and the stigmas became receptive before the corolla opened (Fig. 2), and it was not unusual for the corolla to fail to expand altogether. Flowers of this type were mostly female-fertile, producing a normal crop of seed when pollinated artificially. In a few instances auxin

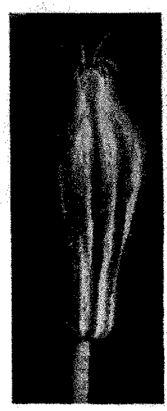

Fig. 2. Intact male-sterile flower of *S. pendula* var. *ruberrima* from an auxin-treated branch of a plant flowering in long days after an interlude of 50 short days, showing the precocious emergence of the styles, the arrested corolla, and the inflated calyx surrounding the abnormally enlarged ovary. (× *c.* 2·5)

Table 3. Effect of α-Naphthaleneacetic Acid on Male Fertility in *Silene pendula* var. *ruberrima*

Sterility of anthers in all flowers formed on the single treated lateral in each plant compared with that in a sample of 100 flowers from untreated branches of the same plant. Treatment details as in text

Plant No.	Untreated laterals per cent sterile anthers (100 flowers)	Treated laterals No. of flowers	Treated laterals per cent sterile anthers
*SR*5	0·9	5	98·0
*SR*7	0·0	4	100·0
*SR*13	0·3	5	100·0
*SR*15	0·9	2	100·0
*SR*17	1·3	2	100·0

treatment through the leaves resulted in parthenocarpy, capsules being formed directly without opening of the flower and without pollination.

Of the small numbers of fully or partly male-fertile flowers formed on the auxin-treated lateral branches in the experiment with var. *compacta*, most showed strong protogyny, the styles being exserted two to four days before the dehiscence of the anthers. Flowers of the untreated branches of these plants were regularly protandrous.

Cytological aspects of the male sterility induced in *Silene pendula* by photoperiodic and auxin treatments will be described elsewhere ; here it is sufficient to state that morphologically and histologically the effects produced through the two agencies are very much alike. The similarity of the reaction suggests that the influence of photoperiod on sex balance may be exerted through the native auxin metabolism of the plant during the period of flower differentiation, a possibility already indicated by work with short-day species[1,3,7] but still without direct proof based upon auxin assay.

'PURITY' OF GELATIN AS A PROTEIN

By G. RUSSELL
Chemical Research Laboratory, Ilford Limited, Brentwood

BAILEY has recently written[1] that, because of the use of newer techniques, the "most respectable" proteins are turning out to be mixtures. I wish to describe experiments which bring gelatin within this category.

It is generally believed that, neglecting inorganic impurities, gelatin represents a fairly 'pure' protein. This assumption is implicit in much research work on gelatin[2]. Eastoe, for example, regards gelatin as a purified form of collagen[3], the main criterion of purity in this case being constancy of amino-acid composition.

It has long been known that gelatin contains small quantities of proteins similar to albumin. Thus, by heat coagulation, Sheppard[4] was able to isolate small quantities (about 0·5 per cent) of a protein which he identified as being similar to albumin. In later work[5], Sheppard described a process for removing albumin ($\leqslant$ 1 per cent) from gelatin by solvent precipitation, for example, with acetone. Similar results are described by Stainsby[6] for ethanol fractionation. Maron has described[7] the isolation of an albumin-like protein (0·3 per cent) by treatment of gelatin with active charcoal.

Following the application of Sheppard's technique of heat coagulation[4] to samples of gelatin, we wished to use some less-destructive procedure for assessing the effects of any purification methods which might be suitable for gelatin. The first procedure attempted was chromatography of the whole (unhydrolysed) protein on ion exchange resin columns as described by Boardman and Partridge[8]. The following work applies to high-grade lime-processed gelatins with iso-electric points[9] in the region of pH 5. The resin used was 'Amberlite *XE*-97', 200–400 mesh in a column 16 cm. high and 1 cm. diameter. Runs were carried out either on 1 ml. of 0·5 per cent w/v gelatin solution (= 5 mgm.) for analytical purposes or 2 ml. of 2·5 per cent w/v gelatin solution (= 50 mgm.) for preparative purposes. Buffer was passed through the column at 4 ml./hr. and 1 ml. fractions were collected on a Locarte fraction collector. Analysis was usually carried out by acid hydrolysis of the fractions, followed by a colorimetric ninhydrin procedure[10] for total amino-nitrogen. Occasionally, a modified biuret procedure[11] was also used.

When the resin was buffered at pH 7 or pH 6 (McIlvaine buffer), and the column was eluted at this pH, the major part of the protein was fairly rapidly removed from the column, as shown in Fig. 1 (left). When the pH of the resin and of the eluting buffer was reduced to 5·5, a much lower peak was observed (Fig. 1, right). The remainder of the protein was not eluted at pH 5·5 up to 250 fractions either at 25° C. or 35° C., nor did shortening the resin column to 5 cm. allow it to be eluted. It must

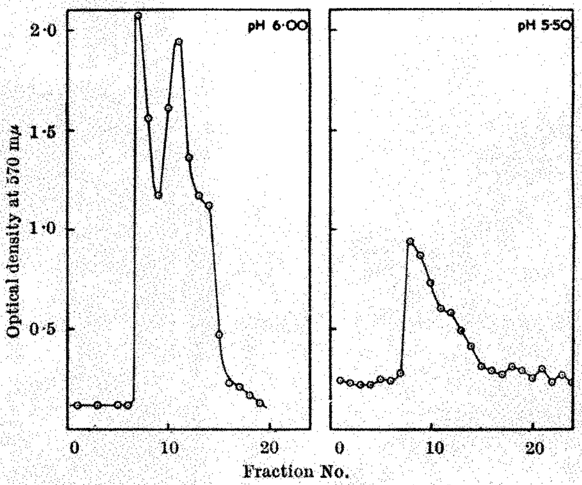

Fig. 1. Behaviour of gelatin on a 16 cm. × 1 cm. column of 'Amberlite *XE*-97' at different pH's

be concluded that it is very firmly bound by the resin at this *p*H.

Changing the *p*H of the buffer to 6 or 7 after elution of the first peak did not produce a great effect because of the considerable buffering capacity of the resin. However, if, after elution of the peak mentioned, the run was continued with 0·1 *N* sodium hydroxide at 35° C., the *p*H of the effluent rose rapidly to 8 and simultaneously the remainder of the protein began to come off the column (Fig. 2).

This procedure, therefore, has divided the gelatin into two fractions. It is estimated that the total ninhydrin colour produced by the first peak corresponds to about 15 per cent by weight of the gelatin. The protein in this peak may be isolated by pooling the fractions, dialysis and precipitation with ethanol. In two experiments, the yield of protein obtained in this way was 15 and 19 per cent, respectively. The isolated protein was examined qualitatively by paper chromatography. This showed that the protein resembled serum albumin and differed from gelatin in the following respects. It contained no hydroxyproline and only a low concentration of glycine. Tyrosine was easily detectable. Hydroxylysine was absent. Cystine was only present in traces as it is largely destroyed by the liming treatment in gelatin manufacture[12] (Fig. 3).

The question of tyrosine content is an interesting one. According to Eastoe[3], the tyrosine content of gelatin is very variable and may represent the extent of contamination by another protein. This view is shared by Harkness *et al.*[13]. I have carried out tyrosine determinations by direct measurement in 0·1 *N* sodium hydroxide in the ultra-violet[14]. The tyrosine content of the group of gelatins studied varied from 0·31 to 0·54 per cent on an air-dry basis. The tyrosine content of the protein eluted at *p*H 5·5 was not accurately determined, but was about 3 per cent; the protein eluted at *p*H 8 contained very little detectable tyrosine (lower limit of detection 0·01 per cent). This would imply that the concentration of the other protein in the gelatins studied varied from 10 to 18 per cent.

The implications of such a finding are many. It may be that either an inter-protein complex or a definite impurity of possibly variable concentration is present. In the latter case, such studies as N-terminal amino-acid groups, gelatin structure and amino-acid sequence may be regarded as of doubtful validity. The present conceptions of other properties such as surface activity, adsorption and viscosity of gelatin solutions may also be influenced by the new evidence. A discussion of such implications as well as a more detailed account of the present work will be given elsewhere.

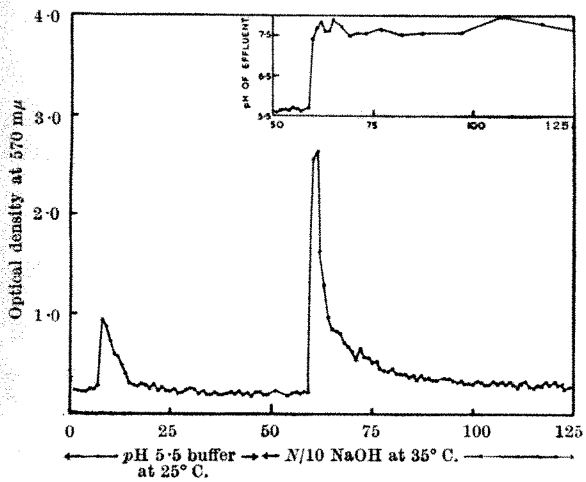

Fig. 2. Elution of two peaks from 5 mgm. gelatin. The upper portion (inset) shows the *p*H changes in the effluent when the sodium hydroxide run begins

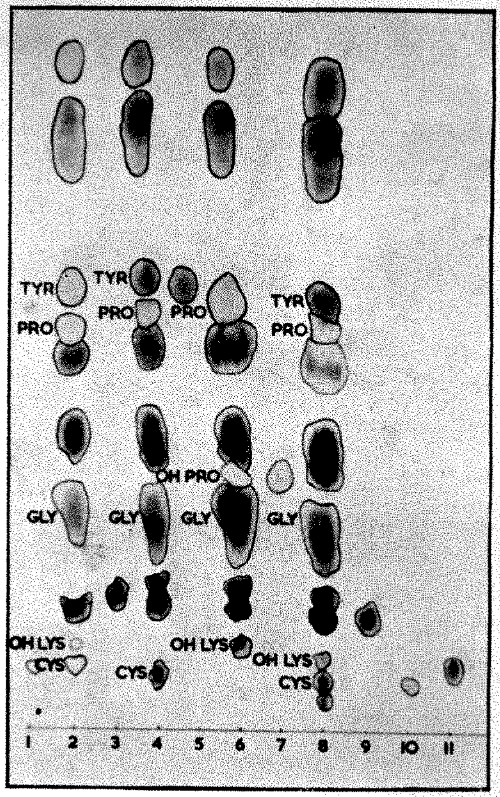

Fig. 3. Paper chromatogram of various protein hydrolysates (descending, Whatman No. 1, butanol-acetic acid). Detection by ninhydrin

1, Cystine; 2, protein eluted at *p*H 5·5; 3, lysine; 4, blood albumen (B.D.H.); 5, tyrosine; 6, gelatin; 7, hydroxyproline; 8, heat-coagulated protein, according to Sheppard (ref. 4); 9, lysine; 10, cystine; 11, hydroxylysine. Zones shown dotted are very faint

Technical assistance in the present work was given by Mrs. B. Ormerod and Miss M. E. Bell. I should also like to thank Mr. A. G. Ward, director of research at the British Gelatine and Glue Research Association, and members of his staff for valuable discussions.

Observations in Australia of Radio Transmissions from the First Artificial Earth Satellite

THE choice by the U.S.S.R. of frequencies of 20 and 40 Mc./s. for radio transmissions from their Earth satellites provided a new approach to the study of the ionosphere, the main interest of the Radio Research Board in Australia. So arrangements were made to record the intensity variations of the signals.

The Overseas Telecommunication Commission generously made available a low-noise site and good receiving facilities at Bringelly, near Sydney.

The 20 Mc./s. signal was recorded using a quarter-wave vertical dipole antenna, a sensitive stable highly selective receiver, and a Brown high-speed potentiometric pen recorder. Observation was confined mainly to times when the signal was received by a direct path and was no longer modulated by the $\frac{1}{3}$ sec. modulation.

A 60-sec. sample of one record is shown in Fig. 1. It will be noted that there is a slow signal variation with sensibly constant period of the order of 5 sec. and a faster deep fading of variable periodicity.

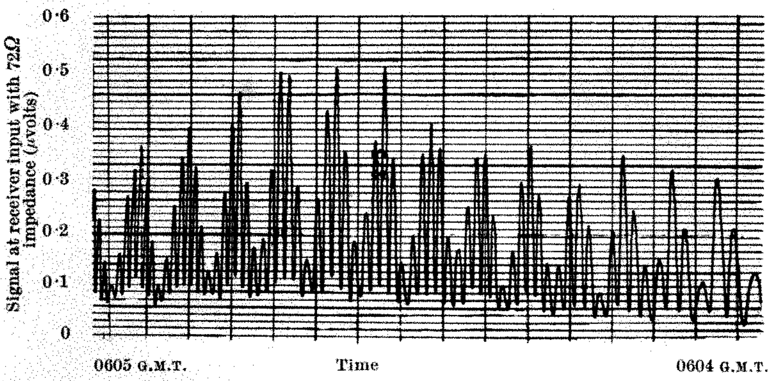

Fig. 1. Strength of 20 Mc./s. signals from satellite α1957 recorded at Bringelly, N.S.W., Australia, on October 19, 1957, at 0604–0605 G.M.T.

The faster fading-rate varies according to a regular pattern which is shown plotted in Fig. 2 for three close transits. It can be seen that the rate passes through a minimum which occurred always to the south of the observing station. There are also points of inflexion in the curves which occur at times when the satellite is near to the position of closest approach to the station as deduced from Doppler shift measurements.

The south to north transits were at a height of approximately 500 km. and from north to south they were at approximately 900 km. For the north to south transits only one record has been found which shows both sides of the minimum.

The minimum appears to occur when the satellite position is such that the propagation of the wave is nearly perpendicular to the direction of the Earth's magnetic field; but more accurate orbital information than is at present available is needed to establish this precisely.

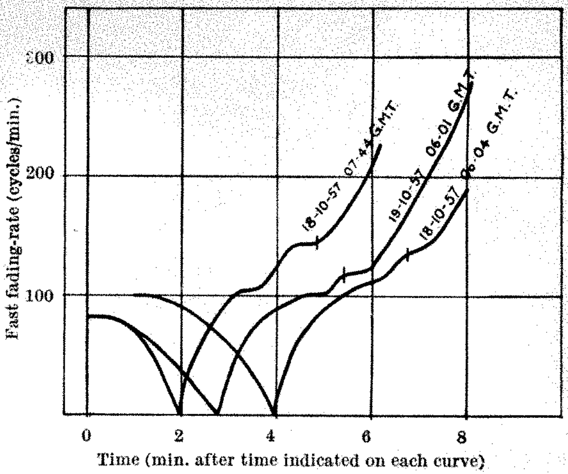

Fig. 2. The fast fading-rate of the 20 Mc./s. signal of satellite α1957 as a function of time during south to north transits. Vertical stroke, time of nearest approach to station

Similar effects appear to be present on 40 Mc./s. records which were made simultaneously with the 20 Mc./s. measurements; but the recordings were made with less satisfactory equipment. The slow fading pattern, because of its regularity, is considered to be a feature of the transmission, possibly due to rotation of the satellite. There seems little doubt that the fast deep fading is due to interference between the ordinary and extraordinary components as the respective received phases vary due to a combination of variation in path difference and Doppler frequency shift difference for the two components. The relative magnitude of the two effects has not yet been computed.

In addition, the depth of the beats has enabled calculation of the relative strengths of the two components as a function of time and hence of the relative absorption in the ray paths. Due to attenuation of the extraordinary component the fading at the time when the fading rate is a minimum is small so that if the attenuation was high or the transmitted signal weak, this portion of the curves was not recorded.

Theoretical examination and detailed computation are continuing in anticipation of accurate information on the satellite orbit being obtained.

Propagation of Radio Waves from Cosmical Sources

WHEN a radio wave passes through an un-ionized medium its ray path is rectilinear. On passing through such ionized layers, which usually surround the Earth, its trajectory is satisfactorily determined by Snell's law:

$$\mu\rho \sin i = \rho_{\parallel} = \sin i_0 = \text{constant} \qquad (1)$$

which is valid for any point of the ray path. For the sake of simplicity the radius of curvature ρ_m of the maximum of electron density is taken as the unit of length. The significance of the parameters used follows from Fig. 1.

According to (1) and Fig. 1, the rectilinear part of the ray path must be tangential to the sphere defined by $\rho_{\parallel}$, everywhere in the un-ionized medium. Thus a ray which passes through spherical ionized layers of the same centre of curvature O is turned about this centre of curvature by the angle R (Fig. 1).

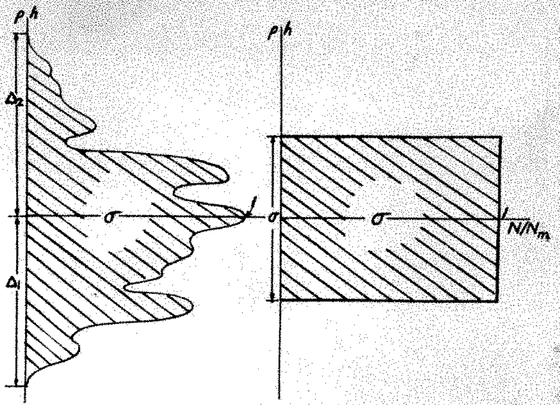

Fig. 2. The true and the equivalent layer, introduced in order to avoid discrepancies that could appear as the electron density is usually expressed in cm.[3] while the introduced unit of length is ρ_m. In this equivalent layer having the same contents of electrons and the same N_m, the electrons are squeezed together in order to form a layer of uniform electron density (N_m). The thickness of this equivalent layer $\sigma > 1$ is to be introduced into formula 2

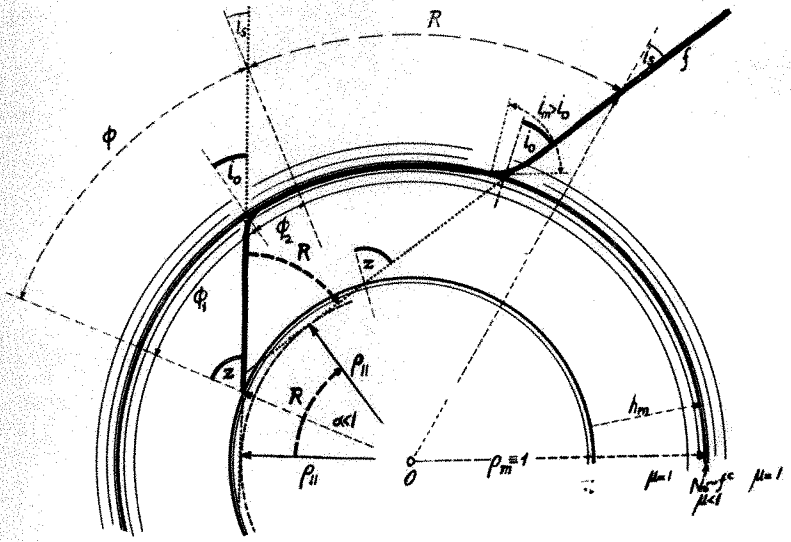

Fig. 1. Parameters used in formulæ 1 and 2. f is the wave frequency, f^c the critical frequency of the layer,

$$\mu = \sqrt{1-\left(\frac{f^c}{f}\right)^2} \text{ and } \rho = \frac{6{,}400 \text{ km.} + h}{6{,}400 \text{ km.} + h_m}$$, h and h_m being in km.

For this angle of refraction R the following simple formula has been derived[1]:

$$R = \frac{90^\circ}{\pi}\left(\frac{f^c}{f}\right)^2 \frac{\sin i_0}{\cos^3 i_0} \cdot \sigma \qquad (2)$$

where again $\rho_m = 1$, i_0 is the angle of incidence of the rectilinear parts of the ray path, related, however, to this level $\rho_m = 1$, and the equivalent thickness σ of the layer is to be determined according to Fig. 2.

Formula 2 is valid for $\dfrac{f^c}{f \cos i_0} < 0{\cdot}4$ and $\Delta < \rho_m/5$.

For $f^c/f \cos i_0 > 0{\cdot}4$ the true refraction is greater than the calculated one, and it increases to infinity; this case, dealing with a perpetual propagation of radio waves around the Earth along one of the two different levels of the ionosphere, has been treated previously[2].

The refraction formula 2 has the advantage that it depends only upon the total content of all free electrons present in the layer, but not upon the irregularity in electron distribution with height, which up to the present time has made the calculation of refraction uncertain. Formula 2 is valid even for sharp gradients of electron density, and for parabolic types of layer, $\sigma = \frac{4}{3}\Delta$, it goes over into Bailey's formula[3].

The theoretical result, mentioned above, is in good agreement with experimental results obtained from the signal records of the first artificial satellite. The angular distance of the satellite $\varphi + R$ was determined from formulæ 1 and 2 and Fig. 1 as follows:

$$a \sin z = (a + h_m) \sin i_0$$

$$\sin i_{\text{sat.}} = \frac{a}{a + h_{\text{sat.}}} \sin z$$

$$\varphi_1 = z - i_0, \quad \varphi_2 = i_0 - i_{\text{sat.}}$$

$$\varphi = \varphi_1 + \varphi_2 = z - i_{\text{sat.}}$$

and $\sin i_0 \leqslant \mu_m\rho_m$ corresponds to the minimum of the $\mu\rho$-curve. In accordance with the calculated values the received signal disappeared usually sooner on 20 Mc./s. than on 40 Mc./s., and only in cases when the signal was coming from countries where for 20 Mc./s. $f \doteq f^c$ was long-distance propagation of the signal around the Earth from the magnetic equator observed.

Summarizing, the rectilinear part of a ray path becomes rotated about the centre of curvature of the ionized layer through which it has penetrated by the angle of refraction R. This deviation R depends only upon i_0, f^c/f and the content of free electrons present in the whole layer, but it is independent of their distribution.

Free Acid in British Soils

Under the humid climate of northern and western Britain organic materials often accumulate as *mor*[1] humus layers on well-drained woodland soils or as bog peats in wetter locations. Both types of humus are characteristically very acid, and this communication examines the possibility that sulphuric acid is mainly responsible for their low *p*H values.

To study this question in the wetter habitats, water samples were collected from pools on seven areas of bog, listed in order of increasing hydrogen ion concentration in their waters: Cooran Lane, Galloway; Druimbasbie and Strathy, Sutherland; Rannoch Moor; Tregaron, Cardiganshire; Dergoals and Kilkahockadale, Galloway; Moor House, Cumberland; Coom Rigg, Northumberland. All exhibit a good cover of *Sphagnum* moss, a sign that the peats are very wet and in a more or less natural condition. Moreover, they are so deep and extensive that the bog surfaces probably depend for their ion supply almost wholly upon the atmosphere.

Hydrogen ion concentration in the seven areas ranges from 0·03 to 0·13 m.equiv./l., averaging 0·066 m.equiv./l.; while sulphate ranges from 0·06 to 0·24 m.equiv./l., and averages 0·133 m.equiv./l. The coefficient of correlation (r) between free hydrogen ions and sulphate is 0·964, a highly significant value which may be increased by taking into account the appreciable amount of sulphate reaching the bogs in blown sea spray. This fraction may be estimated by assuming all chlorides in these waters to be derived from sea spray[2,3], and dividing the chloride values by 9·7—the ratio of chloride to sulphate in sea water. On subtracting the sea spray contribution from total sulphate, the correlation coefficient between hydrogen ions and the remaining sulphate becomes 0·985. Such a high coefficient strongly suggests that the low *p*H values of these bog waters are indeed due to sulphuric acid. A similar correlation has been observed for individual pools within the Moor House bog[4]. The regression of hydrogen ions upon corrected sulphate in the seven bog areas follows the formula $y = 0{\cdot}556x + 0{\cdot}006$.

The highest acidities are recorded from bogs near industrial areas, while the lowest come from sites remote from industry. Since fuel combustion produces large amounts of sulphur dioxide, which oxidizes to sulphuric acid, bog acidities are directly increased by industrial development nearby. Ringinglow Bog outside Sheffield provides an extreme example, with water analyses from this bog—now in a far from natural state—yielding hydrogen ion and sulphate concentrations of 0·57 and 0·96 m.equiv./l. respectively. In this connexion also, the influence of air pollution on rain acidity is clearly evident in the English Lake District, where the *p*H of precipitation averages less than 4·5 and may occasionally[2,3] go below 4·0.

It may be noted that in these bog waters hydrogen ions are only equivalent to 61 per cent of sulphate (exclusive of that from sea spray). In the Lake District rain the proportion is rather similar.

The free acid in *mor* humus layers was investigated by expressing the soil solution, with the aid of a hydraulic press, from sixteen samples collected in Lake District oakwoods on Silurian substrata. These *mors* overlie heavily leached mineral soils transitional between brown earths and podzols, and exhibiting strong profile development[1].

Hydrogen ion concentration in the *mor* waters ranges from 0·02 to 0·36 m.equiv./l., averaging 0·109 m.equiv./l.; while sulphate ranges from 0·26 to 1·01 m.equiv./l. and averages 0·508 m.equiv./l. The correlation between free hydrogen ions and sulphate (after subtraction of sulphate from sea spray) is again highly significant, with $r = 0{\cdot}872$. Once more, sulphuric acid seems likely to be the main factor responsible for low soil *p*H values, and must greatly enhance leaching. The regression of hydrogen ions upon corrected sulphate follows the formula $y = 0{\cdot}307x - 0{\cdot}033$.

The association between hydrogen ions and sulphate is stronger for the bog waters than for the *mor* soil solutions ($r = 0{\cdot}985$ as against 0·872). Moreover, the proportion of sulphate balanced by hydrogen ions is much greater in the bog waters than in the *mor* solutions (61 as against 24 per cent). It seems likely that an appreciable part of the *mor* acid is neutralized by bases from mineral soil particles embedded in the humus, in which case a lower correlation between hydrogen ions and sulphate is not surprising. It may also be remarked that the average corrected sulphate level in the *mors* (0·46 m.equiv./l.) is considerably above the highest bog value (0·24 m.equiv./l.), owing probably to concentration of the interstitial water in these well-drained soils by evaporation.

As in the case of the bog waters, air pollution can account for much of the free acid in Lake District *mors*[3]. However, even in areas without much industry, sulphuric acid will probably be produced from decomposing organic sulphur compounds[5]. Support for this view may be found in the inter-correlations between free hydrogen ions, sulphate and dissolved organic carbon in waters of Nova Scotian lakes, draining acid peaty soils on substrata low in lime[6].

In conclusion, it must be pointed out that the *p*H values of both bog waters and *mor* soil solutions are a good deal higher than those obtained by direct insertion of a durable glass electrode into fresh soil. For example, at Moor House the *p*H range of 3·7–4·1 for six surface pools may be compared with a range of 3·3–3·9 for eight fresh peats from the same area; while the *p*H range of ten Lake District *mor* solutions, 3·8–4·6, may be compared with a range of 3·2–3·5 for the fresh soil. The much lower *p*H values of the fresh soils are presumably due to a 'suspension effect' on the glass electrode by hydrogen ions adsorbed on soil colloids. Exchangeable hydrogen ions are abundant in both woodland *mors* and bog peats[1,7], and must be, like the sulphuric acid free in solution, of great importance for soil development.

Influence of Water-Content of Sand on Rate of Uptake of Rubidium-86

The relationship between nutrient absorption and the moisture content of the soil has been the object of numerous investigations. Complications arise, however, if an attempt is made to disentangle the separate processes involved. The growth of the plant itself is strongly influenced by the moisture content of the soil and the ionic equilibria between

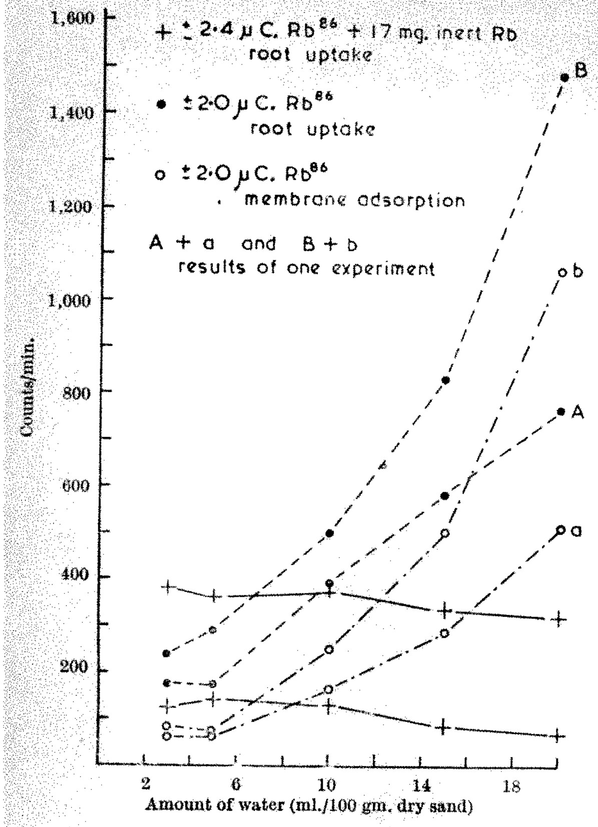

Fig. 1. Uptake of rubidium-86 by excised roots of *Vicia faba* (+ and ●); and by a cation resin membrane, 'Permaplex *C*-10' (○) from 100 gm. dry sand containing a varying amount of water (3–20 ml.)

the adsorbed ions and those in solution undergo a change. Another difficulty encountered is the fluctuation in moisture content of the soil as brought about by transpiration and watering, so that the conditions are not constant during the experiment.

The problem has recently been investigated by Dean and Gledhill[1] and by Danielson and Russell[2], who used techniques to eliminate a number of complications. Their results, however, are contradictory in some respects.

Dean and Gledhill[1] used excised rootmats of young rye seedlings that were pressed upon sand containing a fixed amount of labelled phosphate. One of their findings is that uptake can decrease with an increase of moisture content of the sand, although the reverse may also occur.

Danielson and Russell[2] made use of very young corn seedlings completely buried in the soil. They find that the ion uptake decreased rapidly with initial increases in soil moisture tension, and levelled out at higher tensions to give a curve nearly logarithmic in nature.

An attempt was made to extend our knowledge on the influence of the amount of moisture on the rate of uptake by means of a technique which eliminates complications to a great extent.

The experiments were performed with excised young root pieces of the broad bean (*Vicia faba*), which were taken from the primary laterals of plants cultivated in tap-water. A batch of twenty-five root pieces was buried in 100 gm. of washed sand to which ±2 μc. rubidium-86 was added and a varying amount of water. In part of the experiments a varying amount of inert rubidium chloride was added besides the tracer amount. Experiments lasted about twenty-four hours and were mostly conducted at room temperature.

The results demonstrate that if only a minute amount of rubidium is present in the sand, the uptake greatly increases as the amount of water rises from 2–20 ml. If, however, a larger amount of inert rubidium is added the reverse trend is found and uptake decreases somewhat with increasing moisture content (Fig. 1).

The following explanation seems justified, and is in agreement with experience gained in work with other ions.

As long as the sand contains only a very small amount of rubidium (not exceeding ±4 mgm./100 gm. of sand) the layer in direct contact with the root cannot furnish enough substance to meet the demands of the root. So the rate of uptake will be dependent on the number of ions able to diffuse towards the root from more distant layers. As the moisture content of the sand rises, this diffusion is enhanced, as has been shown by Klute and Letey[3], and uptake increases. The purely physical nature of this response can be demonstrated by the fact that a cation exchange membrane reacts in exactly the same way (Fig. 1).

If, however, the amount of rubidium in the sand is higher, the moist layer surrounding the root will contain more substance than the root can absorb during the experiment. As the sand can be considered as a practically inert medium, the concentration of the rubidium in solution will vary inversely with the amount of water added. Uptake is now governed by the concentration of rubidium in solution in the pore space. So the rate of uptake diminishes somewhat with an increase in the amount of water added.

Thus the relation between moisture content of the medium and rate of uptake depends on the amount of soluble substance. At low concentrations of rubidium the rate of uptake is enhanced by increased moisture content and at higher concentrations the rate of uptake is somewhat lowered.

Age Determinations of Southern Ocean Waters

A model of Southern Ocean circulation has been provided by Deacon[1] based on that for the South Atlantic and supported by detailed observations made during the cruises of R.R.S. *Discovery II*. On this model, cold dense water forming in the Weddell Sea sinks to the ocean floor to form Antarctic bottom water which exhibits northward and eastward components of motion.

In December 1956 and January 1957 we obtained twenty-gallon samples of bottom water at each of the two stations in the Southern Ocean south of New Zealand. Sampling was carried out from

H.M.N.Z.S. *Pukaki* in the course of an investigation by the New Zealand Oceanographic Institute of the Antarctic convergence and the hydrology of the Ross Sea sector of the Southern Ocean.

The stations were located as follows: (1) Lat. 64° 54′ S., long. 178° 10′ E., 150 miles north of Scott Island (N.Z. O.I. Station B27, 28.12.56). Depth to bottom 3,000 m., depth of sample 2,643 m. (2) Lat. 53° 38′ S., long. 169° 52′ E., 100 miles south-east of Campbell Island. (N.Z. O.I. Station B32, 1.1.57.) Depth to bottom 800 m., depth of sample 765 m.

The apparent carbon-14 ages of these samples were determined by Mr. T. A. Rafter and Mr. G. J. Fergusson in the Nuclear Sciences Division, N.Z. Department of Scientific and Industrial Research: the ages were 2,540 ± 100 years and 1,900 ± 100 years respectively for samples 1 and 2.

The southern station (B27) is located on the north-facing slope leading from the Pacific Antarctic Ridge into the Pacific Antarctic Basin. The station is 500 miles from the nearest Antarctic coast and a somewhat lesser distance north of the average northern limit of Antarctic land. The northern station (B32) is over the Campbell Plateau, south of New Zealand. Here the general depth is 400 fathoms and the Plateau rises steeply from depths greater than 2,000 fathoms to the south and west.

At Station 2 and adjacent to Station 1, temperature–salinity–oxygen profiles were sampled, to bottom at Station 2 and to 2,000 m. near Station 1, the deepest water sampled in the latter case being in the 'warm deep' layer[1]. The carbon-14 sample from Station 1 has come from the boundary zone between Antarctic bottom water and the southward moving 'warm deep' current. Consideration of the hydrological observations obtained at the same time as these samples is being prepared for publication.

Apparent ages of deep Atlantic water have been reported by Kulp[2], the maximum age being 1,950 ± 200 years for a sample from 4,663 m. in the north-west Atlantic. Cooper[3] has pointed out a number of factors, the re-cycling of 'old' water, the time required to achieve equilibrium with the atmosphere and physio-chemical 'ageing' with increase in temperature, which affect direct application of apparent carbon-14 ages to determinations of rates and nature of oceanic circulation systems.

If the generalized model of Southern Ocean circulation be accepted, then, whatever the true age of the water mass from time of formation, the total time which a significant proportion of the water mass sampled has been shielded from the atmosphere could be very great: in high southern latitudes northward-moving deep water will have an apparent age principally determined by the apparent age at formation and the time since sinking.

The Campbell Plateau sample has been obtained from an area in which upwelling induced by the submarine topography could operate to give the high apparent age.

These initial observations are now being continued by the N.Z. Oceanographic Institute over these and more northerly latitudes. The present isolated observations at least suggest that: (1) the value of the latitudinal component of movement of bottom water is low; (2) the total turnover time of ocean circulation systems is of the order of thousands of years; (3) the present oceanic circulation may be found to be complicated by factors inherited from a late Pleistocene hydrological environment.

Manganese Deposition and Deep Water Movements in the Caribbean

In the course of a study of the chemical composition of certain deep-sea cores, particular attention has been paid to one such core (*A* 179–4) collected south-west of Hispaniola in 2,965 m. at lat. 16° 36′ N., long. 74° 48′ W. in the Caribbean and subjected by Emiliani[1] to oxygen-18 : oxygen-16 palæothermometry.

The material of this core is predominantly calcium carbonate with varying quantities of lithogenous sediment. There is no correlation between variations in either calcium or the major lithogenous constituents (silica, iron, aluminium, titanium) and temperature. The major lithogenous constituents exhibit variations highly correlated *inter se*, though there seems to be a slight systematic rise in titanium relative to the other constituents throughout the period of deposition of the sediment, which embraces, on Emiliani's interpretation, most of the Pleistocene.

The manganese content, however, is entirely unrelated to the lithogenous group of constituents or to calcium. Inspection of the graph (Fig. 1) indicates that manganese is inversely, if somewhat irregularly, related to surface temperature. The correlation coefficient of manganese on temperature, namely, −0·511, is, in fact, highly significant (with 35 pairs of observations, $P \simeq 0{\cdot}001$).

Since manganese is the only abundant constituent likely to be sedimented by purely chemical process in the Atlantic Ocean or adjacent seas, its independent behaviour is not surprising; but the nature of its distribution raises the question as to why it should tend to precipitate at this station more rapidly during glacial than during interglacial periods.

We believe that the best explanation is to be found in Goldberg's[2] hypothesis that colloidal manganese dioxide is deposited electrophoretically in

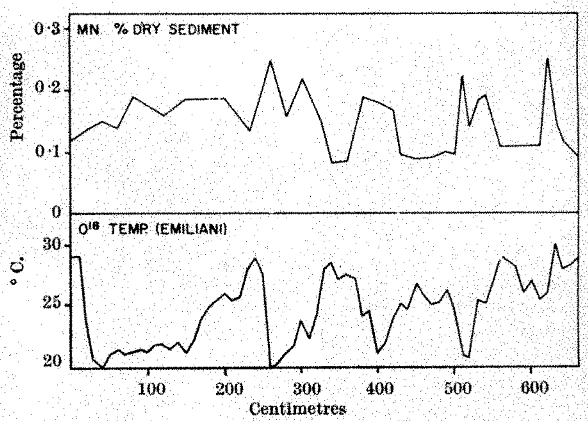

Fig. 1

regions of potential gradient set up as water containing charged particles moves through the Earth's magnetic field. The rate of deposition will clearly depend on the velocity and direction of the current. We consider, therefore, that the enhanced deposition of manganese in this part of the Caribbean during glacial periods is probably due to enhanced water movements related somewhat irregularly to glaciation. The most reasonable type of movement would presumably be the spilling of cold water over the rim of the Caribbean basin. Non-steady state movements of this type are becoming recognized[3] as features of deep water circulation in various parts of the Atlantic. If our hypothesis proves reasonable, variation in manganese content in deep water sediments should throw considerable light on the incidence of such movements throughout the Pleistocene and possibly during more remote periods of the history of the ocean.

We are indebted to Prof. Maurice Ewing and to Dr. David B. Ericson of the Lamont Laboratory, Columbia University, and to Dr. Cesare Emiliani of the Marine Laboratory, University of Miami, for the opportunity to study this material. The work was supported by contract from the Office of Naval Research. A detailed report on the analyses will be published by one of us (P. J. W.) later.

Grain Boundaries and Electroluminescence in Gallium Phosphide

Some interesting properties of gallium phosphide have been studied in polycrystalline specimens kindly provided by H. Welker, of Seimens Schuckertwerke, Erlangen. Etching of the surface has revealed grain boundaries, and annealing twins. Etch pits have also been observed along slip lines.

Electroluminescence has been reported previously[1], but that observed here shows unusual features, in that the light sources form a pattern of narrow lines and are identifiable with grain boundaries. Most sources are found in the surface, though sheets of light have been observed, joining more intense sources in opposite faces. Not all boundaries luminesce, and on reversal of the current the light pattern changes markedly. Voltage probing shows that a large and constant proportion of the total applied voltage is developed across the luminescent boundary. Electroluminescence is also observed at a cathode point contact to the *p*-type gallium phosphide, indicating that minority carrier injection and radiative recombination occurs. It is proposed that this is the mechanism responsible for the grain boundary luminescence, and that impurity segregation at the boundary creates an *n*-layer between the *p*-type grains. This forms a *p–n–p* junction, or two *p–n* junctions 'back-to-back', and minority carrier injection and consequent radiative recombination occurs at whichever is the forward-biased junction. A junction of this sort in the grain boundary would account for the observed voltage distribution, and the results of current-voltage studies are in agreement with the theories of Shockley and Prim[2] and Dacey[3] for *p–n–p* structures.

The observation of etch pits along slip lines indicates the possibility that these pits are formed at the points of emergence of dislocations, which would be of considerable interest. Further, if impurities at grain boundaries are responsible for electroluminescence, this phenomenon may prove a useful tool by which to study impurity atmospheres during boundary migration.

Reaction of Carbon Monoxide with Graphitic Carbon at 450° C.

Published investigations of researches on the reaction of carbon monoxide with carbonaceous solids have been concerned with the Boudouard reaction, $2CO \rightleftharpoons C + CO_2$. Many measurements have been reported above 500° C. in which range the rate of reaction is appreciable and the resultant partial pressure of carbon dioxide is measurable. Below 500° C. the observed partial pressure of carbon dioxide is so low that it cannot be differentiated experimentally from that normally expected on outgassing such materials, although the equilibrium values for the carbon dioxide are higher than those above 500° C.

Experimental conditions have now been discovered whereby an appreciable reaction occurs between carbon monoxide and some graphites at 450° C. However, carbon dioxide is not formed. The sample was contained in a 'Vycor' tube through which purified carbon monoxide was circulated. Traces of water vapour were continuously removed by liquid nitrogen traps on both sides of the sample tube. When necessary each sample was previously treated with hydrochloric and hydrofluoric acids to assure the absence of metallic impurities as evidenced by spectrochemical analyses. It was then heated for 20–40 hr. with evacuation at either 450° or 700° C. and then cooled in the latter case to 450° C. before the introduction of carbon monoxide. A definite chemisorption of the carbon monoxide was observed. A more significant result was the formation of a carbon deposit downstream at locations well beyond the bed of graphite. Mass-spectroscopic analyses proved the almost complete absence of gases other than carbon monoxide even after the liquid nitrogen was removed. A chemical analysis of the deposit demonstrated it to consist of carbon.

The following mechanism could account for these observations. The first step is the chemisorption of a carbon monoxide molecule. A second carbon monoxide molecule is then chemisorbed to the chemisorption complex, which then reacts to form gaseous carbon suboxide, C_3O_2. This serves to transport the carbon atoms of the graphite through and out of the bed of sample. Carbon suboxide is unstable at the temperature of the reaction and decomposes in one or more steps to deposit carbon and liberate carbon monoxide.

The first implication of these results is that at a temperature as low as 450° C., small amounts of carbon monoxide can cause migration of carbon atoms and, thus, in a sufficiently long time, could re-form an appreciable fraction of the graphite into a possible new crystalline or amorphous form. Thus far, appreciable reaction has been observed only with graphites which have been irradiated in nuclear reactors, while unirradiated graphite, charcoal, etc., showed only very small traces of carbon transport or none at all. Thus, it is possible that the added energy in the irradiated graphite, and the accompanying structural changes, is responsible in some way for this effect. Further work is needed to prove that only irradiated graphite can produce this transport.

An Electronic Mechanism of Addition Reactions

IT has now become abundantly clear that in ethylene ($CH_2{=}CH_2$) one of the two bonds is of the normal covalent type (σ-bond), while the other belongs to a distinct and separate class (π-bond). Thermochemical studies have further revealed that the bond-strength of a C=C double bond is appreciably less than twice the value for a C—C single bond, showing that the π-bond is not as strong as the σ-bond. Thus it was quite natural to assume that addition reactions occur by the direct rupture of the weaker π-bond. However, it has been found that addition proceeds generally in the *trans* sense, which is exactly contrary to expectation. The reactivity towards addition reactions also decreases unexpectedly with increase in the number of π-bonds (except in conjugation). Acetylene ($CH{\equiv}CH$) with two π-bonds is less reactive than ethylene[1]. The first stage addition to one of the cumulated double bonds in allene ($CH_2{=}C{=}CH_2$), which is expected to be very much strained, is also much slower than the second stage addition to its remaining simple double bond[2]. It is remarkable that higher cumulenes ($>C{=}C{=}C{=}C{=}C{=}C<$) are quite stable[3].

It is thus generally realized that the π-bond itself is not the seat of any weakness in the molecule[4]. It may be that the σ-electrons are in some way connected with this subtle and devious attack on the multiple bonds. It has been found that electrophilic groups retard addition reactions (as in $HOOC{-}CH{=}CH{-}COOH$), while electron repelling groups accelerate them (as in $CH_3{-}CH{=}CH_2$)[4]. These groups are attached to the carbon atoms of the double bond through σ-bonds. As such, they can affect the reactivity only by depleting or by supplementing the σ-electrons of these carbon atoms. This argument is further supported by the fact that the retarding effect of the electrophilic groups on the reactivity of acetylene derivatives is very small (as in $HOOC{-}C{\equiv}C{-}COOH$)[5], because it is difficult to withdraw σ-electrons from a triple bond which itself is strongly electrophilic. On the basis of all these considerations it can be postulated that the initial attack in addition reactions occurs on the σ-electrons and the reactivity of the unsaturated molecule depends upon the σ-electron density of the carbon atoms. This concept of addition mechanism through σ-electrons is also in agreement with the fact that frequently substitution and addition occur side by side. At high temperatures substitution increases at the cost of addition. Furthermore, the electrophilic groups also retard substitution in benzene. They de-activate mainly the *ortho* and *para* positions and thus become meta-directing.

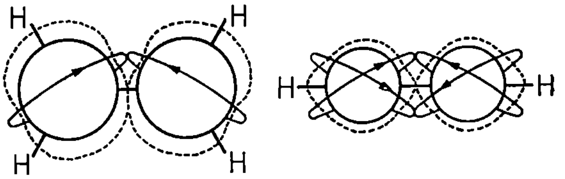

Fig. 1. Electronic structures of ethylene and acetylene. The broken line shows the distorted σ-electron density

It now remains to find the cause of enhanced reactivity of the σ-electrons in unsaturated molecules. It appears that the π-electrons somehow cause this activation of σ-electrons. As the quantum-mechanical approach has not yet succeeded in solving this problem, it may be worth while to develop a tentative speculative explanation based on simple physical concepts. It is generally agreed that the π-electrons can be regarded, from many points of view, as forming a separate shell 'outside' the other electrons[6]. I have gone a step farther in postulating that the planes of the π-electron orbits remain fixed[7]. They couple at an angle which causes the restriction on the free rotation of their orbital planes. Probably the high electron density between the two carbon atoms due to the σ-bond does not permit the exchange of two more (π) electrons through the same region (Fig. 1).

The spherical symmetry of the σ-electron density of the carbon atom becomes distorted as a result of the fixation of π-electron density around it. On the particle concept of the electron, these distortions of σ-electron orbits would be unsteady and non-uniform. Some of the σ-electrons may become deviated (due to repulsion from the fixed π-electron orbit) much more than others. These abnormally deviated σ-electrons may bond an extra atom temporarily. This sudden electronic disturbance would break the π-bond, and one of the π-electrons set free is utilized in forming a stable covalent bond with the addendum. The π-electron on the other carbon atom remains free for a while and becomes saturated through a distinct second phase of addition. This interval provides scope for steric rearrangements giving *trans* products. In the fast reactions the *cis* products predominate. In some of the molecules one of the atoms already present may be knocked out in favour of the new entrant, thus causing substitution. In benzene, substitution is relatively easier than addition as the π-bond in it is stronger than in simple multiple bonds[8].

The distortions of the σ-electron orbits would be proportional to the σ-electron density on the carbon atom. This explains the lower reactivity of acetylene (two σ-electrons per carbon atom), and the retarding effect of electrophilic groups. The central atoms in cumulenes, containing only two σ-electrons each, act as electrophilic groups on the reactivity of the end CH_2-groups[9]. The activating effect of such groups as CH_3 does not appear to be due to electron donation, as they increase the reactivity of acetylenic compounds to only a very small extent. They appear to have an obstruction effect which increases the abnormal distortions of σ-electron orbits in other directions.

Other aspects of unsaturated molecules, such as bond-lengths, Pascal's constitutive correction factor λ for the multiple bonds, etc., have been discussed in terms of these concepts elsewhere[7,8].

Infra-Red Absorption of OH Bonds in Micas

IN favourable cases, infra-red absorption spectra afford a valuable adjunct to diffraction methods in crystal structure analyses. The structures of the micas have been familiar for many years, but have never included any specification for the site of the proton in the constitutional hydroxyls.

In the biotite micas (such as phlogopite, $K_2(Si_6Al_2)Mg_6O_{20}(OH)_4$), if one assumes tetrahedral environment for oxygen, three of the tetrahedral hybrid orbitals are involved with magnesium neighbours, the bond to the proton must have its axis normal to the cleavage, and steric factors preclude that the proton has a secondary association with any other oxygen. In muscovite,

$$K_2(Si_6Al_2)Al_4O_{20}(OH)_4,$$

only two orbitals are involved with aluminium neighbours, and the O—H bond axis could be normal to the cleavage as above, or could be directed toward the unoccupied cation site, thus lying no more than 15–20° inclined to the cleavage, and probably favourably disposed for secondary association with one or both near oxygen neighbours as an O—H . . . O bond.

The efficiency of absorption in the frequencies associated with the O—H bond is a function of the angle between the bond axis and the plane of the electric vector of the light. For normal incidence on a phlogopite cleavage flake, there is no resultant along the OH bond axis and no absorption in the region of the OH stretching frequency. With increasingly inclined incidence, absorption increases regularly with the increasing resultant of the plane of the electric vector on the bond axis. The observed frequency for unmodified OH stretching is 3,710 ± 20 cm.$^{-1}$. When muscovite is examined similarly, strong absorption is observed for normal incidence at 3,620 ± 20 cm.$^{-1}$, and the absorption is not markedly sensitive to moderate tilting of the flake. It is concluded that the O—H bond axis must have one or more of the orientations near the plane of the cleavage flake for the dioctahedral composition, and that the lesser frequency may be evidence of some hydrogen bonding.

A third case illustrates the precision of observations. Lepidolites present frequent instances in which analyses suggest that a trioctahedral lithium-bearing biotite and a typical muscovite are intimately parallel grown. Spectra at normal incidence and at increasingly inclined incidence to the lepidolite illustrated show absorption at the muscovite frequency with little sensitivity to orientation and absorption at the phlogopite frequency with sensitivity to orientation as in phlogopite.

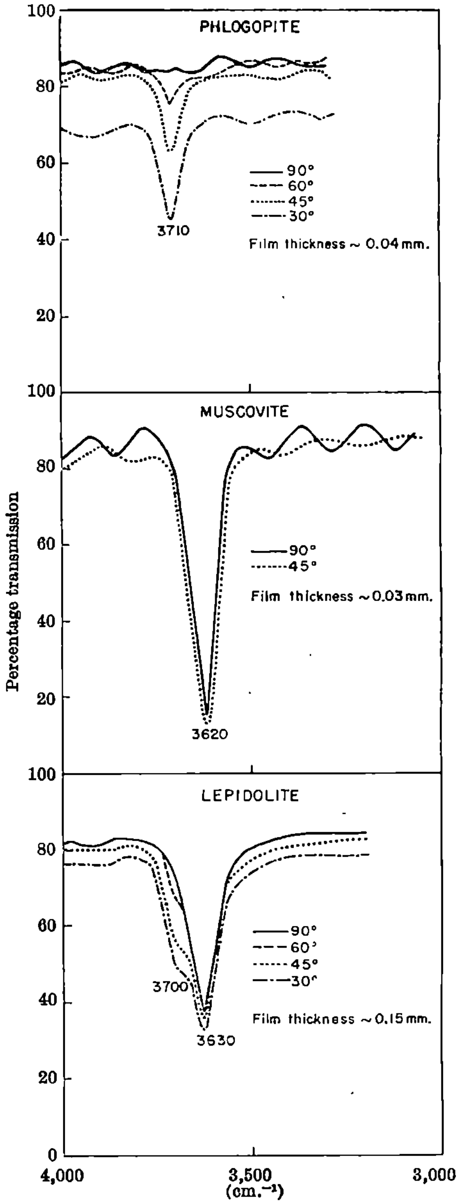

Fig. 1. Infra-red spectra of phlogopite, muscovite and lepidolite for cleavage flakes oriented at different angles to the incident beam

The spectra in Fig. 1 were recorded with a Perkin-Elmer Model 21 double-beam spectrometer with a sodium chloride prism.

We have recently learned that a more elaborate analysis, in substantial agreement with our present communication, was conducted during the War by Dr. G. B. B. M. Sutherland for the U.S. Army Signal Corps, but not published.

The Pyridine Ring and the Problem of its Biosynthesis

THE relationships of anthranilic acid and tryptophane to nicotinic acid are well established in a number of organisms[1] and it has been suggested that in the higher plants the pyridine ring may be formed in a like manner[2]. It has been shown, however, that tryptophane-3-^{14}C is not a precursor of damascenine in *Nigella damascena* L., nor did it give rise to radioactive trigonelline when fed to pea seedlings[3]. It is possible that in the two plants studied the enzyme system necessary for the initial oxidation of tryptophane to kynurenine is lacking and that the hydroxyanthranilic acid in one case (damascenine) and the pyridine ring in the other (trigonelline) are synthesized from different precursors and by a different pathway.

These two cases, however, do not exclude the possibility that in some other plants tryptophane might be the precursor of the pyridine ring. It has been claimed that *Nicotiana tabacum* does not utilize tryptophane in the biogenesis of the pyridine ring of nicotine[4], but the location of the carbon-14 in the labelled tryptophane used was such as to make it very unlikely that it would appear in the nicotine. Since the present work has been completed, however, Leete[5] has shown that tryptophane labelled in the benzene ring at the position to which the nitrogen is attached is not utilized by *N. tabacum* in the formation of nicotine. Further, 3-hydroxyanthranilic acid, a metabolite of tryptophane, does not serve as a precursor of trigonelline when fed to excised soybean leaves[6].

It was of interest to determine whether a plant that cannot utilize tryptophane in its synthesis of the pyridine ring might be able to convert anthranilic acid (also a metabolite of tryptophane in certain moulds) into the pyridine ring since the initial oxidation of the tryptophane would be by-passed. Chemically, there is no reason why anthranilic acid as well as kynurenine could not be hydroxylated. We have now tested this point with regard to nicotine formation in *Nicotiana tabacum* var. White Mammouth fed with anthranilic acid-1-^{14}C. The carbon-14 label, however, was not transferred to the nicotine isolated from these plants.

The starting material used for the synthesis of anthranilic acid was toluene-1-^{14}C (purchased from Tracerlab Inc., Boston, Mass.). Nitration followed by oxidation of the resulting nitrotoluenes with permanganate afforded a mixture of nitrobenzoic acids from which most of the *p*-isomer was separated as its sparingly soluble copper salt[7]. Catalytic reduction of the recovered crude *o*-nitrobenzoic acid yielded anthranilic acid which was precipitated from neutral solution as its insoluble cobalt complex[8]. Treatment of the complex with hydrogen sulphide liberated very pure anthranilic acid which was isolated with ether, sublimed and crystallized from water from which it separated as needles, m.p. 144–145°.

The tobacco plants were grown from seed in soil for two months and then transferred to a nutrient solution prepared as described by Leete[9], but modified by substituting ferric tartrate as the source of iron. The nutrient solution was aerated continually and changed weekly. It was necessary to add further quantities of ferric tartrate (4·0 mgm. per l.) twice a week to suppress signs of iron deficiency in the plants. After three weeks, five plants were each suspended in a quantity of the nutrient solution and anthranilic acid-1-^{14}C (300 mgm.) of specific activity $1 \cdot 1 \times 10^7$ disint. per min. per m.mol. was divided equally between the five solutions. After 10 days of contact the nutrient solutions (total activity $1 \cdot 65 \times 10^6$ disint. per min.) were discarded and replaced by fresh solution (without labelled material). Eighteen days after feeding the anthranilic acid the plants were harvested, extracted with dilute hydrochloric acid and the nicotine separated from this extract (total activity $4 \cdot 8 \times 10^6$ disint. per min.) by distillation from alkaline solution[10] followed by precipitation as the dipicrate. Nicotine dipicrate crystallized from 30 per cent dimethylformamide as yellow needles, m.p. 223–224°, unaltered by mixture with an authentic sample. A quantity of the dipicrate was converted to the diperchlorate separating from the ethanol as needles, m.p. 207–208° either alone or in admixture with an authentic sample. Paper chromatography[11] showed nicotine to be the only pyridine base detectable in the crude plant extract. The nicotine salts showed no significant radioactivity.

From Leete's work[9] there is no doubt that the tobacco plant synthesizes nicotine at the stage of growth at which the present experiments were performed. Hence anthranilic acid does not function as a precursor of the pyridine ring of nicotine. Surprisingly, lysine does not give rise to the pyridine ring of nicotine either[9], nor is it the precursor of the α-pyridone ring of ricinine (Reist, E. J., and Marion, L., unpublished results). A body of evidence is, therefore, accumulating according to which it seems improbable that in the higher plants the pyridine ring would have its source in either tryptophane or lysine, which appeared to be the two most plausible precursors. It is true that according to Dawson *et al.*[12] the preformed pyridine ring (nicotinic acid) can be utilized by the plant in the synthesis of nicotine; but this does not seem to have much bearing on the initial formation of the pyridine structure. It now appears likely that the pyridine ring might be built directly from smaller units arising from alanine and glycine, or possibly from non-nitrogenous precursors, and ammonia. In micro-organisms where tryptophane functions as the precursor of nicotinic acid, the pyridine ring must arise by ring closure of an oxidative intermediate compound, which in the higher plants might be built up at a much faster rate from smaller units than it can be formed from the metabolites of tryptophane. The fact that nicotinic acid takes part in the biogenesis of nicotine[12], whereas tryptophane does not[5], lends support to this possibility, which is being investigated.

A Quantitative X-Ray Study of Alpha-Beta Transformation in Keratin

The first X-ray diffraction studies of the α–β transformation in keratin were made by Herzog and Jancke[1] and Astbury and Street[2]. Since then it has occupied a pivotal position in all attempts to determine the molecular structure of proteins. Recently, Bendit[3] has reported the variation of the peak intensity of the 5·1 A., 4·6 A. and 9·8 A. reflexions against percentage extension for Lincoln wool and concluded therefrom that Astbury's hypothesis of a molecular transformation based on a 1 : 1 correspondence of the intensity variation of the first two reflexions is not tenable. However, no quantitative X-ray study of the degree of order introduced with extension has been yet reported.

The outstanding reflexions in the alpha-photograph of human hair are the meridional strong arc of spacing 5·15 A., made up of (020) flanked on either side by (120), and the composite equatorial reflexions (001), (101), (300) and (201), spread over 3 A. and having a mean spacing of 9·8 A. The (100) reflexion, because of its proximity to the centre and poor definition, does not lend itself to an easy evaluation and is therefore omitted. During the course of transformation from alpha to beta, which sets in at about 30 per cent extension, the meridional arc begins to close up while there appears on the equator a new spot of 4·65 A., and the overall definition of the photograph also improves. However, the dark arc never completely disappears. If we denote the total intensity of the meridional and equatorial spots by I_m and I_e, respectively, then the degree of order, Ω, may be defined by the relation :

$$\Omega = \frac{I_e - I_m}{I_e + I_m} \times 100$$

This expression has the advantage of being independent of all exposure factors.

In order to carry out an experimental determination of this degree in three different varieties, X-ray photographs, using copper K_α radiation, monochromatized by reflexion from a calcite crystal, were taken of bundles of human hair well-combed to ensure parallelism and held taut between two pin-vices one of which was movable and carried a screw-gauge to measure extension. The fibres were always stretched in water at room temperature and supercontracted by stretching first in steam and later allowing them to recover in steam itself. Intensity measurements were made by Moll's recording-type microphotometer and they were reduced to the same scale. The results obtained are shown in Table 1.

These results show that the change is exponential. Initially there is a rapid rise in the degree of order, but from 60–70 per cent extension the change is not very large. The behaviour of golden hair is much nearer to that of black than to that of white. The difference may be due to the presence of air bubbles in white hair. On treatment with cuprammonium hydroxide it was found that the fibre-pattern disappeared completely because of the contraction arising from an extra folding of the chains induced by co-ordination of the absorbed copper with appropriate groups in the keratin chain. A study of this 'reversible super-contraction' produced on washing with dilute sulphuric acid is also being made, and a detailed account of the work will be published elsewhere.

Table 1

Variety	Super-con-tracted	Un-stretched	Stretched (per cent)			Treated with cuprammon-ium hydroxide
			40	60	70	
Black	38·13	43·97	51·9	53·19	54·09	0
Golden	37·58	41·8	48·01	50·12	51·12	0
White	34·21	37·03	43·82	45·83	46·60	0

Fibrous Structure in Cheese Curd

In the manufacture of Cheddar cheese the curd granules fuse under gravity into solid blocks, usually 6–12 in. in thickness. At the same time some spreading or flow of the blocks takes place. This flow appears to be responsible for the characteristic fibrous texture in the 'cheddared' curd. In designing a curd-fusing or cheddaring machine Czulak and Hammond[1] took account of this fact and arranged, following initial compression into a solid block, to submit the curd to pressure in a longer chamber, thereby giving flow in one direction. Curd cheddared in this machine has a greatly increased longitudinal fibrous structure, strips of curd some 20 in. in length being readily torn from the block.

Microscopic examination by fluorescence methods of sections of the curd cut parallel to the direction of flow shows a network of long casein fibrils of a minimum thickness of 0·1μ. The picture at a magnification of about 1,400 resembles that of coagulated blood fibrin as shown in the electron photomicrograph of Wolpers and Ruska[2]. In sections cut transversely to the direction of flow, or in curd

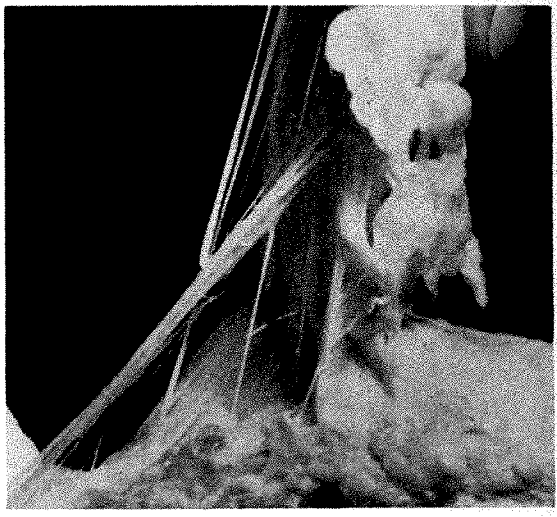

Fig. 1

which has not been submitted to flow, few of these fibrils appear.

The electron micrographs of Imhof and Hostettler[3] show that, following a linear aggregation of casein micelles (each micelle containing about 1,000 casein molecules) at the initial coagulation of the milk by rennet, fusion of the micelles occurs during the later stages of the cheesemaking process. The electron micrographs of Baud, Morard and Pernoux[4] seem to indicate the formation of appendages which afterwards serve to join the micelles during coagulation. The fibril formation which we have observed could be explained by the orientation of the separate casein molecules (axial ratio about 8 : 1) and their more or less end-to-end attachment, or more readily by some uncoiling of the polypeptide chains. The flow of the curd mass could itself contribute to this uncoiling, since proteins may be denatured by mechanical shearing action.

First and Second Cycle Casein in Milk

The component of the casein complex which, according to Waugh and Von Hippel[1], is responsible for the colloid chemical stability of the casein micelles in milk is *k*-casein. The same authors have also given its preparation, as follows. The casein in skim milk is precipitated by addition of calcium, and by subsequent removal of calcium from the precipitate a solution of the so-called 'first cycle casein' is obtained. This first cycle casein contains β-casein and the α/*k*-complex. Reprecipitating first cycle casein with 0·25 *M* calcium chloride at 37° C. results in the splitting of the α/*k*-complex and hence in the chemical instability of the casein micelles in the colloid. The precipitate was named 'second cycle casein', and it no longer contains the protective *k*-casein in stabilizing quantities. The latter can be isolated from the remaining supernatant of second cycle casein. In its physico-chemical properties, such as electrophoretic mobility, diffusion and ultracentrifugation characteristics, *k*-casein was shown to resemble α-casein closely.

The present communication deals with an electrophoretic study of first and second cycle caseins both with and in the absence of the milk-clotting enzyme rennin.

From an earlier investigation by Nitschmann and Lehmann[2] with acid-precipitated casein it is known that the rennin action electrophoretically is characterized by the splitting of the α-peak into two distinct components, namely, α_1- and α_2-casein, with nearly the same mobilities. We have repeated the Nitschmann/Lehmann experiment both with first and second cycle casein.

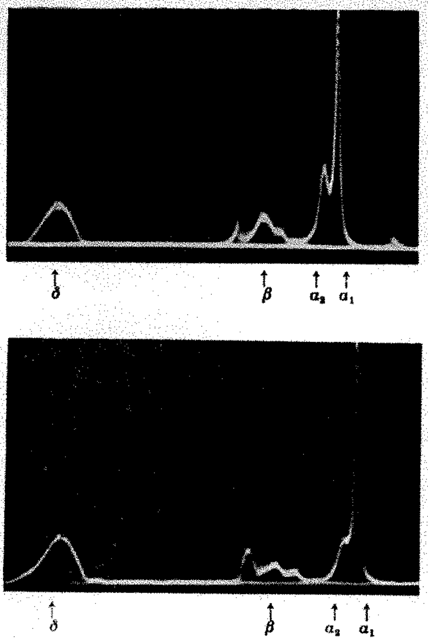

Fig. 1. Ascending electrophoretic patterns of first and second cycle caseins after 4,800 sec. Conditions of experiment: protein concentration, 1·7 per cent; Michaelis buffer *p*H = 7·3, Γ/2 = 0·1; field strength, 9·75 V./cm.; 2° C. Above: first cycle casein, active rennet solution added; below: second cycle casein, active rennet solution added

Table 1

Exp.	Substrate	Rennet	α_1/α_2 split	α_2 (per cent)	$\mu_{\alpha_1} \times 10^5$ (cm.²/V./sec.)
A	First cycle casein	Heat-inactivated	Occasionally	27	8·98
B	Second cycle casein	Heat-inactivated	Unseparated	13	10·90
C	First cycle casein	Active solution	Very pronounced	29	9·05
D	Second cycle casein	Active solution	Pronounced	14·5	10·70

The caseins were incubated at 35° C. with a solution of commercial rennet powder (1 : 100,000) of the N.V. Chemische Industrie Van Hasselt, Amersfoort, Holland. The rennet concentration was chosen such that 10 mgm. rennet were added per gram of casein. In this way its concentration is too low to be distinguished electrophoretically. For comparison heat-inactivated enzyme was also added to first and second cycle casein. The experiments were repeated several times. A typical set of experiments are summarized in Fig. 1 and Table 1, which show that α_2-casein is much less abundant in second cycle than in first cycle casein. These results suggest that α_2-casein is closely related to the *k*-casein of Waugh and Von Hippel: possibly the two components are actually identical.

Additional support for this conclusion is found in a comparison of the mobilities of the α_1-component in first and second cycle casein (Table 1, column 6). The mobility of the α_1-casein is considerably higher in second ($10 \cdot 80 \pm 0 \cdot 1 \times 10^{-5}$ cm.²/V./sec.) than in first cycle casein ($9 \cdot 02 \pm 0 \cdot 03 \times 10^{-5}$ cm.²/V./sec.). Obviously this mobility increase is due to the decrease in α_2-content in the second cycle and the accompanying decrease in α_1/α_2-interaction.

Arylsulphate Synthesis and the Arylsulphatases

DURING the course of studies on the synthesis of sulphate esters an opportunity was taken to obtain evidence to support the suggestion[1] that the type II mammalian arylsulphatases (arylsulphatases *A* and *B*)[2] were unlikely to be directly involved in the synthesis of arylsulphates by particle-free mammalian liver preparations. It has already been pointed out[3] that the type I arylsulphatase of mammalian livers (arylsulphatase *C*) cannot be directly involved in this synthetic process since the enzyme is microsomal in origin and highly insoluble. Similar considerations do not apply to the type II enzymes, however, since although they are mainly associated with the so-called 'light mitochondria', appreciable amounts are always present in preparations of the soluble components of the liver cell[4].

The arylsulphate-synthesizing system of mammalian livers is known to involve at least two main steps; the production of an active form of sulphate (3′-phosphoadenosine-5′-phosphosulphate) and the subsequent transfer of the sulphate group of this compound to a phenolic acceptor via the agency of a specific transferase enzyme. Particle-free rat-liver preparations[5] of this synthetic system contained appreciable amounts of the type II arylsulphatases. The average activity of the dialysed preparations was such that 1 ml. liberated 2 μmole nitrocatechol/hr. at 37·5° from 0·005 *M* dipotassium 2-hydroxy-5-nitrophenyl sulphate (nitrocatechol sulphate) in 0·5 *M* acetate buffer, *p*H 5·0 (conditions favouring arylsulphatase *A* activity) and 4 μmole nitrocatechol/hr. from 0·02 *M* nitrocatechol sulphate in 0·5 *M* acetate buffer, *p*H 6·0 (conditions favouring arylsulphatase *B* activity). For various reasons[2] these values can only be regarded as approximations. When fortified[6] with adenosine triphosphate and magnesium and sulphate ions and incubated in the presence of 0·05 *M* phosphate buffer, *p*H 7·0, the dialysed preparations were capable of synthesizing approximately 0·1 μmole *p*-nitrophenyl sulphate, nitrocatechol sulphate or *p*-acetylphenyl sulphate/hr./ml. from the respective parent phenols.

Further purification of the system by ammonium sulphate fractionation according to the directions of Segal[5] concentrated both the synthetic and the arylsulphatase activities. However, no loss in type II arylsulphatase activity occurred when the system synthesizing 3′-phosphoadenosine-5′-phosphosulphate was destroyed by treatment with glycylglycine[6] or when the enzyme system responsible for transfer of sulphate from 3′-phosphoadenosine-5′-phosphosulphate to the phenolic acceptor was inactivated by heat treatment[6]. Purified samples of mammalian arylsulphatases *A* and *B* also showed no loss in activity when subjected to these inactivation procedures. Addition of these purified samples to the arylsulphate-synthesizing system decreased the activity of the system slightly, while addition of the purified soluble type I arylsulphatase of *Alcaligenes metalcaligenes*[7] strongly inhibited the synthetic process. This is not surprising, since the hydrolytic activity of this bacterial enzyme is unaffected by the phosphate and sulphate ions present in the synthesizing incubation mixture whereas the hydrolytic activity of the type II mammalian arylsulphatases is considerably inhibited by these ions.

It seems probable, therefore, that the arylsulphatases cannot be directly concerned in the synthesis of arylsulphates via 3′-phosphoadenosine-5′-phosphosulphate, and these conclusions are supported by the recent observation (Spencer, B., personal communication) that incubation of purified samples of mammalian arylsulphatases *A* and *B* with *p*-nitrophenol in the presence of 3′-phosphoadenosine-5′-phosphosulphate did not effect any sulphate synthesis.

One of us (H. B.) is grateful to the Medical Research Council for a research assistantship.

Effect of Chymotrypsin on Cæruloplasmin

INTEREST has been shown in the blue, copper-containing, serum oxidase cæruloplasmin, in particular because of its absence from the blood of subjects with hepatolenticular degeneration[1]. The copper of cæruloplasmin is firmly bound, being non-dialysable at neutral *p*H [2]. As part of a study of the mode of linkage of copper to the apo-enzyme, the effect of chymotryptic digestion on cæruloplasmin was investigated.

Cæruloplasmin was prepared from the *G*2 plasma fraction of Kekwick and MacKay[3] using a modification of the method of Kominz[4]. The final blue material had a broad absorption peak with maximum at about 610 mμ. Copper content was determined by a diethyldithio-carbamate method[4] and cæruloplasmin content calculated from Holmberg and Laurell's[2] finding of 0·34 per cent copper in cæruloplasmin. Purity was about 70 per cent. An amount of the material containing 20 mgm. cæruloplasmin was digested with 3 mgm. 'Armour' chymotrypsin in 10 ml. 0·05 *M* *p*H 7·5 sodium phosphate buffer—0·10 *M* sodium chloride at 37° for 22 hr. At intervals during digestion, optical density at 610 mμ was measured and aliquots taken to which tetra-ethyl pyrophosphate was added to inhibit chymotrypsin. Oxidase activity was determined colorimetrically using N,N-dimethyl *p*-phenylene diamine as substrate (see caption to Fig. 1). Non-dialysable copper was also determined on three aliquots. Results are shown in Fig. 1. Enzymic activity and the blue 610-mμ peak decreased during digestion until after 22 hr. they were negligible. (The residual absorption at 610 mμ after 22 hr. was no longer a peak and was part of a spread of the normal protein 280-mμ peak into the visible range. This spread seems characteristic of copper proteins[5]. The 610-mμ peak of cæruloplasmin is destroyed by ascorbic acid[2], but the 610-mμ optical density after 22 hr. digestion was found to be unaffected by ascorbic acid.) Non-dialysable copper also decreased during digestion, but after 22 hr. it was about half that of the original cæruloplasmin.

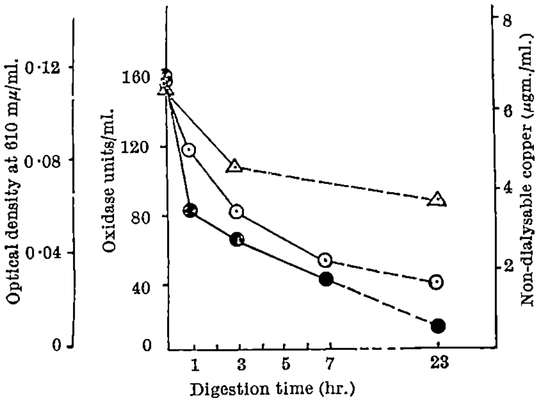

Fig. 1. Effect of chymotryptic digestion on cæruloplasmin oxidase activity, optical density at 610 mμ and non-dialysable copper. ●, Oxidase activity; ⊙, optical density at 610 mμ/ml.; △, non-dialysable copper.

Oxidase activity was determined by adding 2·0 ml. 0·2 *M* *p*H 5·5 sodium acetate–acetic acid buffer to 1·0 ml. cæruloplasmin solution in 0·10 *M* sodium chloride and incubating at 37° for 15 min. with 1·0 ml. fresh aqueous 0·025 per cent N,N-dimethyl *p*-phenylene diamine dihydrochloride. The oxidase reaction was stopped by 2·0 ml. 0·05 per cent aqueous sodium azide and the red colour measured at 550 mμ on a *SP*600 spectrophotometer. A blank was run simultaneously. A unit of enzymic activity was taken as the activity of an amount of cæruloplasmin which gave under the above conditions an optical density of 0·10/cm. light path. There is a linear relationship between amount of cæruloplasmin and optical density in the density range 0–0·15

Three further cæruloplasmin samples were digested with chymotrypsin. In all cases blue colour disappeared and non-dialysable copper after digestion was about half the original cæruloplasmin copper (Table 1). In digestion 4, after 65 hr. digestion, an aliquot of the non-dialysable material was taken, the original amount of chymotrypsin present doubled and digestion at 37° allowed to proceed for a further 23 hr. Non-dialysable copper after this second period was 99 per cent of that after 65-hr. digestion.

The results suggest that of the eight atoms of copper[3] in the cæruloplasmin molecule, four only are in a region that is attacked by chymotrypsin. During digestion, proteolysis of this part of the cæruloplasmin molecule occurs together with loss of blue colour and enzymic activity. The apparent resistance of the other part of the cæruloplasmin molecule to chymotryptic attack may be quite unrelated to its copper component. However, it is known that the iron- or copper-binding protein conalbumen is resistant to chymotrypsin, but only in the iron- or copper-containing forms[6]. Thus it is possible that half the atoms of copper in cæruloplasmin are bound in such a way that they confer chymotrypsin resistance on a portion of the cæruloplasmin molecule.

It is of interest that other workers[7] have recently shown that in the presence of ascorbic acid, half the copper in cæruloplasmin is exchangeable with copper-64. This also implies an accessibility of one half only of cæruloplasmin copper.

I thank the Joint Research Advisory Committee of the Institute of Neurology for financing this work, Dr. J. N. Cumings for help and encouragement and Drs. W. d'A. Maycock and L. Vallet for supplies of *G*2.

*Iso*leucine and Allo-*iso*leucine

DURING our investigations on amino-acid analysis on ion exchange resins using Moore and Stein's method[1], it was seen that in a synthetic mixture of 13 amino-acids (Hoffmann-LaRoche, mostly in the *l*-configuration) the 'methionine' recovery was always too high (120–150 per cent of the theoretical amount) and the '*iso*leucine' recovery always too low (65–70 per cent of the theoretical amount).

On analysing a single sample of '*l*-*iso*leucine' we found two peaks on the chromatogram, the main one in the usual *iso*leucine position and a smaller one at the methionine position (Fig. 1, *B*). According to Piez[2], who succeeded in separating chromatographically a commercial sample of *dl*-*iso*leucine into *d*-*iso*leucine and *d*-allo-*iso*leucine, the 'impurity' is the stereoisomeric allo-*iso*leucine. Piez also found the allo-*iso*leucine coming out of the column at the methionine position.

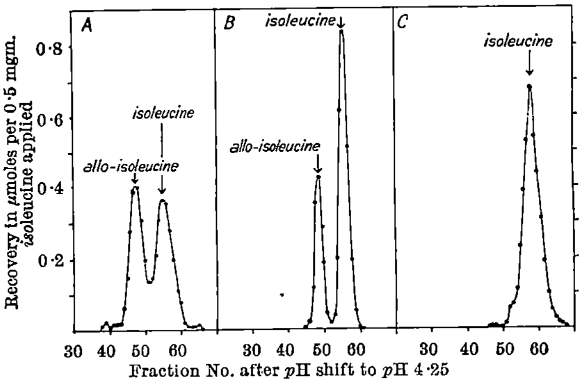

Fig. 1. Chromatograms of samples of: *A*, 0·201 mgm. of *dl*-*iso*leucine (Nutr. Biochem. Corp.); *B*, 0·312 mgm. of *l*(+) *iso*leucine (Hoffmann–La Roche); *C*, 0·530 mgm. of *l*(+) *iso*leucine (Mann Res. Lab.) applied on 100-cm. ion exchange columns containing 'Dowex 50' (*A* and *C*) or 'Zeokarb 225' (*B*). Elution first with 170–200 ml. citrate buffer at *p*H 3·42 ($t = 37·5°$ C.) and then with citrate buffer at *p*H 4·25 ($t = 50·0°$ C.). 1-ml. fractions were collected

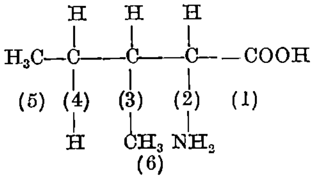
*Iso*leucine has two asymmetric C-atoms (Nos. 2 and 3):



$$\begin{array}{ccccc} & \mathrm{H} & \mathrm{H} & \mathrm{H} & \\ & | & | & | & \\ \mathrm{H_3C}- & \mathrm{C} - & \mathrm{C} - & \mathrm{C} - & \mathrm{COOH} \\ & | & | & | & \\ (5) & (4) & (3) & (2) & (1) \\ & | & | & | & \\ & \mathrm{H} & \mathrm{CH_3} & \mathrm{NH_2} & \\ & & (6) & & \end{array}$$

and consequently has 4 stereoisomeric configurations. These are called *l-iso*leucine, *d-iso*leucine (stereoisomeric with the *l*-configuration at carbon atom 2), *l*-allo-*iso*leucine (stereoisomeric with *l-iso*leucine at carbon atom 3) and *d*-allo-*iso*leucine. In this connexion it may be pointed out that an allo-configuration is also possible for hydroxyproline, hydroxylysine and homoserine (erroneously called threonine by Shulgin[3]), which also contain 2 asymmetric carbon atoms. These allo-configurations have been found by Piez[2], Witkop[4], Hamilton[5] and Shulgin[3].

After chromatographic separation on both 'Zeokarb 225' and 'Dowex 50', with the ninhydrin procedure developed by Moore and Stein[6], for the different analysed *iso*leucines we obtained the following results :

Applied	Ion exchange resin	Found Allo-*iso*-leucine	 *Iso*leucine
0·201 mgm. *dl-iso*leucine (Nutr. Bioch. Corp.)	'Dowex 50'	0·103 mgm.	0·108 mgm. (Fig. 1,*A*)
0·505 mgm. *l*(+) *iso*leucine (Hoffm.–la Roche)	'Dowex 50'	0·132 mgm.	0·331 mgm.
0·312 mgm. *l*(+) *iso*leucine (Hoffm.–la Roche)	'Zeokarb 225'	0·095 mgm.	0·201 mgm (Fig. 1,*B*)
0·502 mgm. *l*(+) *iso*leucine (Nutr. Bioch. Corp.)	'Zeokarb 225'	—	0·475 mgm.
0·530 mgm. *l*(+) *iso*leucine* (Mann Res. Lab.)	'Dowex 50'	—	0·516 mgm. (Fig. 1,*C*)
0·546 mgm. *l*(+) *iso*leucine* (Mann Res. Lab.)	'Zeokarb 225'	—	0·504 mgm.

* Offered as 'allo-*iso*leucine free'

It can be seen that two of the four analysed *iso*leucine preparations consist of a mixture of the two stereoisomers *iso*leucine and allo-*iso*leucine. One sample, which contains no allo-*iso*leucine, was offered as 'allo-*iso*leucine free'. So certainly most of the commercial *iso*leucine samples which give no indications about their allo-*iso*leucine content (and probably all of the *dl* samples) will contain this allo-*iso*leucine in considerable amounts.

Though it is known that out of the four stereoisomeric *iso*leucines only *one* (*l-iso*leucine) can be used by the organism[7], the allo-*iso*leucine content of the commercial *iso*leucine is often neglected in human and animal feeding experiments with *iso*leucine.

We also studied the influence of acid hydrolysis, as used in the analysis of proteins[8], on the stereochemic configuration of *l*(+) *iso*leucine.

We found that hydrolysis with 6 *N* hydrochloric acid does not change the configuration of *iso*leucine. This could be demonstrated by boiling a sample of *iso*leucine free from allo-*iso*leucine (Mann Res. Lab.) for 22 hr. in 6 *N* hydrochloric acid followed by chromatography on 'Zeokarb 225'. The results were :

Applied	Found Allo-*iso*leucine	 Leucine
0·394 mgm. *l*(+) *iso*leucine Mann (Hydr. I)	—	0·371 mgm. (= 94 per cent)
0·134 mgm. *l*(+) *iso*leucine Mann (Hydr. II)	—	0·130 mgm. (= 97 per cent)

There was only one peak, in the *iso*leucine position, and the *iso*leucine recovery was nearly quantitative. No racemization to allo-*iso*leucine took place under these conditions.

In the chromatographic analysis of protein hydrolysates following acid hydrolysis according to Schram[8], the values for *iso*leucine and methionine are not influenced by allo-*iso*leucine formation.

Enzymic Synthesis of Nitrogen-containing Disaccharides by α-Galactosyl Transfer

SEROLOGICAL and enzymic inhibition tests with simple sugars and oligosaccharides of known structure have in recent years given valuable indications about the sugars which are most important for specificity in the complex mucopolysaccharide materials possessing blood-group activity[1]. Di- and tri-saccharides of known structure which are composed of the sugars present in the blood-group substances are required in order to extend these observations ; the enzymic syntheses of two such disaccharides which have not previously been described, α-D-galactosyl-(1→6)-N-acetyl-D-glucosamine (1) and α-D-galactosyl-(1→6)-N-acetyl-D-galactosamine (2), are reported here.

Synthesis of β-linked disaccharides containing amino-sugars was achieved using β-galactosidase preparations from *L. bifidus* var. Penn[2] and *E. coli*[3]. For the present work the α-galactosidase which occurs, with many other glycosidases, in saline extracts of autolysed *Trichomonas foetus* organisms[4] was used as the synthesizing enzyme. Chromatographic examination of the reaction mixtures obtained when melibiose or phenyl-α-galactoside were incubated with *T. foetus* extracts in the presence of large quantities of D-glucose, D-galactose, D-mannose, N-acetyl-D-glucosamine or N-acetyl-D-galactosamine revealed the formation of reducing disaccharides which were absent from the mixture before incubation ; these disaccharides had presumably been synthesized by the enzymic transfer of the α-galactosyl residue from melibiose or phenyl α-galactoside to the second sugar present in the reaction mixture. In the digests containing amino-sugars higher oligosaccharides, which gave positive reactions in tests for N-acetyl hexosamines, were detected in addition to the disaccharides, when melibiose was used as a substrate. In view of the possible use in blood-group studies of the disaccharides containing N-acetylglucosamine and N-acetylgalactosamine these two compounds were prepared on a larger scale for isolation and identification. Melibiose (5 gm.) and N-acetylhexosamine (3 gm.) in 50 ml. of 0·1 *M* phosphate buffer *p*H 6·8 were added to 50 ml. of a freshly prepared *T. foetus* extract and incubated for 18 hr. at 37°. The two disaccharides (1) and (2) were separated from their respective reaction mixtures by chromatography on charcoal : 'Celite' (1 : 1) columns ; each was finally obtained as an amorphous white powder which gave only one spot when examined chromatographically in three different solvent mixtures. The yields were about 600 mgm. of the compound containing N-acetylglucosamine, disaccharide (1), and about half this amount of disaccharide (2). The high positive rotations ((1)$[\alpha]_D$ + 118° ; (2) $[\alpha]_D$ + 142°) supported the belief that the disaccharides possessed α-linkages.

Chromatographic evidence for the constitution of the disaccharides is as follows : enzymic hydrolysis showed that each contained galactose and an N-acetylhexosamine. Reduction with potassium borohydride demonstrated that the compounds were galactosides because on hydrolysis of the reduced disaccharide both (1) and (2) gave galactose and the alcohol of the amino-sugar component. In amyl alcohol : dioxan : water : acetic acid (43 : 34 : 23 : 0·6) solvent mixture, compounds (1) and (2), (R_{glucose} values 0·68 and 0·65 respectively), ran slightly faster than β-galactosyl-(1→6)-N-acetylglucosamine[5] (R_{glucose}, 0·61) and more slowly than β-(1→3)-[6] or β-(1→4)-[7] galactosyl-N-acetylglucosamine (R_{glucose}, 0·75). An α-compound would be expected to run slightly faster than the corresponding β-compound, and this behaviour therefore suggested that (1) and (2) contained α-(1→6) linkages. This suggestion was supported by the colour reaction given with the benzidine–trichloroacetic acid spray reagent[8]. The two new disaccharides each gave a purple-brown spot which was similar in colour to that given by the β-(1→6) compound, but which differed markedly from the golden-brown colour given by the β-(1→4) compound and the greenish-brown colour observed with the β-(1→3) disaccharide. On spraying with alkali followed by Ehrlich's reagent[9] (*p*-dimethylaminobenzaldehyde) (1) and (2) both gave a purple colour indicating a (1→3) or a (1→6) linkage since N-acetylhexosamines which have no free reducing group, or which are substituted at C-4, fail to react with this reagent[10]. Pretreatment of the disaccharides with 0·05 *N* sodium carbonate for 4 min. at 100° before the chromatograms were run resulted mainly in the formation of the disaccharide chromogen without decomposition into the component sugars; this behaviour is similar to that of the β-(1→6) compound[11] and differs from the β-(1→3) which when heated under identical conditions is hydrolysed completely and gives only the chromogen of N-acetylglucosamine. The chromatographic evidence therefore points to the identification of (1) as α-galactosyl-(1→6)-N-acetylglucosamine and (2) as α-galactosyl-(1→6)-N-acetylgalactosamine. The results of periodate oxidation experiments were consistent with these structures since each compound rapidly consumed three molecules of periodate during the first hour of oxidation with a further uptake of three molecules during the next 24 hours, as would be expected for a galactosyl-(1→6)-*N*-acetylhexosamine.

A full account of this work, including the behaviour of these disaccharides in serological inhibition tests, will be given elsewhere.

I am indebted to Dr. Muriel Robertson for generous supplies of *T. foetus* organisms.

Peculiar Distribution of the Diego Factor among the Warrau

THE Warrau are a tribe of South American Indians occupying the Orinoco delta and the adjacent swampy regions of the coast of British Guiana. They have been living in this region since prehistoric times. Being a group of about 9,000 people with a culture fundamentally marginal, they belong to the earliest inhabitants as yet traceable in South America[1].

Two different expeditions were undertaken to the Orinoco delta, in the course of which blood samples were collected from two different Warrau communities: Guayo and Winikina. Genealogical and demographic studies which were executed after we had studied the blood of the Guayo–Warrau group made us suspect that these Indians had some admixture with other Indians, a fact which we then expected to account for the low incidence of the Diego factor among this group. Our expectations were realized after we had tested the Winikina. They are a subgroup stemming from a Warrau subtribe which has been living in complete isolation until very recently.

The present communication is based on 153 blood samples which we had the opportunity of collecting among the Warrau. Genealogical tables at our disposal proved the individuals not to be related with each other. As stated above, the samples were taken from two different Indian communities which are separated from each other by a distance of about 100 km.

Table 1 shows the incidence of ABO, MN, Rh, Duffy and Diego systems of both populations. The blood samples of the Winikina group were also tested with anti-U and anti-Tj^a sera.

The frequencies of ABO and Rh_0 grouping as listed in the chart proved to be in general accordance with previous findings[2]. The frequency of the Fy^a gene coincides with its high occurrence among most of the American Indians. It was a surprise, however, to find both populations with a low incidence of the gene *M*. So far, the Warrau seem to be the only tribe of American Indians known to carry the gene *M* in such a low percentage[3]. The U and Tj^a antigens were positive in all samples of the Winikina subtribe.

The outstanding result of this study was the low incidence of the Di^a antigen among the Guayo–Warrau and the complete negative finding of it among the Winikina–Warrau. The very low occurrence in the first group and negative incidence in the second group cannot be explained by interbreeding with caucasoids or negroids (among whom the Di^a antigen was found to be absent)[4] because the Warrau tested have a frequency of 100 per cent of gene *O* and a negative incidence of the *cde* and *cDe* chromosomes. It is reasonable to assume that the Diego antigen originally has been absent among these Indians and that the positive cases in the Guayo–Warrau were introduced by admixture with Indians carrying the gene; such as the Arawak and Carib, with whom the peripheral Warrau have been in contact since prehistoric times.

Besides the Eskimos[5], the Warrau are the second American tribe which so far seem to lack the Di^a antigen.

Since the incidence of ABO, Rh, Duffy and other blood groups in a great number of American Indian tribes has not shown any significant difference, it is very difficult to determine the interbreeding of two or more tribes from the point of view of blood group-

Table 1. FREQUENCY OF ABO, MN, RH, DUFFY, DIEGO, TJ^a AND U IN THE WARRAU TRIBE

Warrau sub-tribes	No. tested	ABO system				MN system					Duffy system			
		Phenotypes (per cent)				Phenotypes (per cent)			Genes (per cent)		Phenotypes (per cent)		Genes (per cent)	
		A	B	AB	O	M	MN	N	*M*	*N*	Fy(a+)	Fy(a−)	*Fy^a*	*Fy^b*

ing. However, the peculiar incidence of the Diego factor (negative in two, low or high in others[4]) makes it likely that this antigen could be used in future work to determine the rate of interbreeding among them. It is probable that such variable frequency might occur also in Asiatic mongoloid populations.

Hæmoglobin E and the Diego Blood Group Antigen in Sarawak and Burma

A CONSIDERABLE number of simple genetical characters—blood groups and hæmoglobins—are known which distinguish between negroids and caucasoids, but very few have been found which are characteristic of mongoloids. The genes for the Diego (Di^a) blood-group antigen and for hæmoglobin E seem, however, to fall into the latter category.

Hæmoglobin E is characteristic of the peoples of south-east Asia and, as has been shown in preliminary surveys[1,2], the Burmese have the highest known frequency of carriers in the population (15·3 per cent, mainly heterozygotes). With the Burmese may be classed the Siamese[3] with 13·6 per cent, and the Malaysian Malays from eastern Malaya[4] with 13·1 per cent. A second group with lower frequencies includes the less-pure Malaysian Malays from other parts of Malaya[4] (5·0 per cent), the Indonesians[5] (2·6 per cent), and the Veddas[1] of Ceylon, the Bengalis[6] and the Gurkhas[7], among whom only a few instances have been recorded. Among the Chinese, however, extensive surveys have so far failed to show any hæmoglobin E at all. Relatively little work has been done on the hæmoglobins of American Indians, and no abnormal hæmoglobins have been reported in those of unmixed ancestry.

The Diego blood-group antigen was first found in a Venezuelan man[8], later shown to be probably partly of South American Indian ancestry[9]. Owing to the absence of the antigen from any of the white North Americans tested it was at first regarded as a rare familial one, but it was afterwards found to be common in Venezuelan Indians[9] and, later, in other populations. Layrisse and Arends[10] have recently reviewed the literature; combining data from papers cited by them and from other papers[11] we find the antigen to be present in 21 per cent of South American Indians, 10 per cent of North American Indians, 14 per cent of Japanese and 5 per cent of Chinese. It was not found in surveys covering 2,600 caucasoids of various nationalities, but was discovered in a Pole[12] whose wife developed the corresponding antibody through pregnancy immunization. No one with the antigen was found among 35 American Negroes, 156 Eastern Canadian Eskimos, 80 Eastern Polynesians, 162 Australian Aborigines, 23 Eastern Papuans and 74 natives of New Britain.

We have recently examined 185 specimens from Sarawak, 101 from Land Dyaks and 85 from Sea Dyaks (Iban). The Land Dyak specimens were collected from six separate longhouses (villages). The Sea Dyak ones were from recruits to the Sarawak Regiment, coming from numerous longhouses. So far as possible first degree relatives of other subjects tested were avoided. When they were examined for abnormal hæmoglobins all those from Sea Dyaks and all but one from Land Dyaks were found to contain only normal adult hæmoglobin (hæmoglobin A). The exception contained 73 per cent of hæmoglobin A and 27 per cent of a hæmoglobin having the electrophoretic properties of hæmoglobin E. The proportion of the hæmoglobin-A_2 fraction, present in minute amounts in normal blood and electrophoretically indistinguishable from hæmoglobin E, is raised in thalassæmia[13]. In the present instance, however, fœtal hæmoglobin was absent, the red cells were of normal appearance, and, as already indicated, the proportion of apparent hæmoglobin E was more than 20 per cent. From these facts, and the considerations put forward by Aksoy, Lehmann and Lie-Injo Luan Eng[14], it is virtually certain that the sample came from an *AE* heterozygote and not from a case of thalassæmia.

All the Sea Dyak specimens were tested for the Di^a-antigen, the results all being negative; most of them were tested for other blood-group antigens as well. Only 61 of the Land Dyak specimens were in a suitable state for blood grouping, and three of these were found to carry the Di^a-antigen. The full blood grouping results will be published separately.

We have also recently carried out a study of the hæmoglobins and blood groups of the Burmese, the full results of which will be published separately. Some preliminary hæmoglobin results[1,2] have been mentioned above; the full series shows the even higher frequency of hæmoglobin-E carriers of 16·3 per cent. When the main samples were collected, however, we did not have any anti-Di^a serum and we have, therefore, more recently tested a further ten specimens with this serum, with one positive result.

The two characters under consideration, though both, broadly speaking, are confined to mongoloids, have quite different distributions. The Burmese are at or near the centre of the highest frequency of hæmoglobin E, but apparently on the western fringe of the distribution of the Diego antigen. The Land Dyaks, however, from the point of view of the two characters under consideration, may perhaps be regarded as transitional, lying near the eastern margin of distribution of hæmoglobin E but probably, like the Burmese, near the western margin of the Diego area.

The main Diego centre appears to be much farther east, but despite the small numbers tested, our results extend its known area of distribution considerably westward. It is clearly an important indicator of mongoloid ancestry, but its very high frequency among South American Indians and its apparent absence among Eskimos are surprising features which suggest that it may perhaps turn out to be an index of earliness of dispersal from some centre of mongoloid evolution. It is important that tests for this antigen should be carried out on many more Asiatic and Pacific Island populations as well as on larger numbers of Eskimos from all parts of the extensive territory in which they live. In particular, its possible extension to the west of Sarawak and Burma needs to be sought.

We are greatly indebted to Dr. E. Witebsky for the serum used in our tests.

Passage of Serum Albumins from the Mother to the Fœtus

IT has long been recognized that mammals transmit antibodies to their young before the latter are capable of making their own. In current opinion, antibodies are accorded a special status denied to other proteins, and indeed to macromolecules generally, for only antibody protein is generally conceded to pass through the layers of cells separating the maternal and fœtal circulations without undergoing metabolic degradation.

In the rabbit, antibodies are passed to the young during intra-uterine life, a transfer which occurs mainly, perhaps exclusively, via the yolk sac rather than the placenta[1]. Even before a circulation has developed, all the main plasma proteins identified by electrophoresis are present in the yolk-sac fluid, having presumably been transferred as proteins from the maternal blood. The fate of these proteins, whether they are degraded in the yolk sac or afterwards passed into the embryonic blood or tissues, is not known. However, preliminary experiments indicated that bovine serum albumin, or some material of similar antigenicity, appears in the fœtus within twenty-four hours after intravenous injection of the protein into the mother on the nineteenth day of gestation[2]. We have now confirmed this with both bovine and human serum albumins, and have found that proteins retain their original electrophoretic characteristics after passage through several layers of maternal and fœtal tissue. Our observations also indicate that serum albumin can pass directly from the uterine lumen into the exocoele, by-passing the circulation of the yolk sac.

Dutch rabbits (2–2·7 kgm. body-weight) were injected intravenously on the nineteenth or twenty-fourth days *post coitum* with 62·5 mgm. of albumin per kgm. body-weight. Samples of maternal and fœtal blood, and of various other fœtal fluids, were taken with the aid of 'Nembutal' and ether at 1, 6, 24 and 48 hr. after injection. Maternal blood was taken from a uterine vessel, fœtal blood from a vitelline artery or the heart. The fœtal membranes were rinsed with warm saline, dried at one point so that a fine capillary showed no uptake of fluid, and a pipette inserted at the dry point. All fluids were centrifuged to remove cells and tested in two-fold dilutions with specific rabbit antisera. Samples of the fœtal fluids were subjected to electrophoresis on Whatman No. 1 filter-paper strips in veronal buffer (pH 8·6, μ 0·1) for 16 hr. at a constant current of 30 m.amp. One strip was stained with bromphenol blue, and segments of a duplicate strip were squeezed out and the fluids tested with antisera.

Substances with the antigenicity of bovine and human albumins were regularly found in the fœtal sera and migrated with the original mobility of these proteins in close proximity to the fœtal albumin (Fig. 1). Since these substances also formed precipitates with their specific antisera, it is highly probable that the two albumins were not greatly modified as a result of their passage from the mother to the fœtus and through the several fœtal compartments.

The albumins were detectable as early as one hour after injection of the mother and generally increased in concentration during the first 48 hr. (Fig. 2). Blood samples taken at 24 and 48 hr. consistently showed higher titres for the human albumin. This is in accord with the work by Brambell and his associates on the passage of human and bovine antibodies in the rabbit and support their suggestion of a selective mechanism which favours the uptake of human over bovine antibodies. However, human albumin does not appear to be better adapted to penetrate fœtal tissues than bovine albumin. In the fluids of the exocoele, amnion, allantois, and stomach the bovine titres were generally equal to the human titres. Even the apparent selective uptake indicated for the blood vessels may be illusory, the outcome of selective elimination of bovine albumin from the blood into the exocoele. This is suggested by the blood and exocoele titres of the younger fœtuses (19 day series) at 24 and 48 hr., the drop in blood titres being accompanied by a rise in the exocoele.

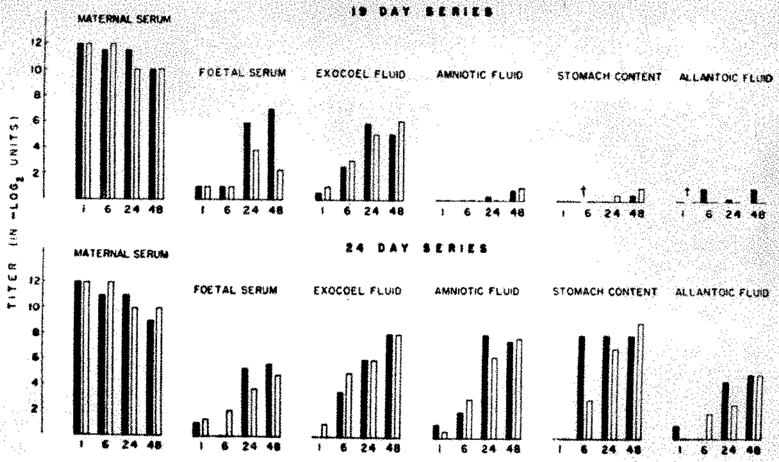

Fig. 2. Foreign albumins in maternal and fœtal fluids at 1, 6, 24 and 48 hr. after intravenous injection of the mother. Titres for human albumin (black bars) and bovine album in (white bars) were obtained with antisera showing a titre of 1 : 1,024 when tested with standards containing 1 mgm. albumin/ml. Each bar represents the average of three to seven samples. A cross indicates no sample tested

A striking difference between the two fœtal stages was found in the fluids of the amnion, allantois and stomach (Fig. 2). In the younger fœtuses these compartments showed little or no foreign protein, whereas the older ones usually had titres as high as, or frequently exceeding, those of the blood. Whatever the means by which the proteins enter or leave these compartments, it is apparent that a radical change in the permeability of the fœtal membranes must occur between the nineteenth and twenty-fourth days of gestation.

When the vitelline vessels were ligated before injection of the mother, the fœtal blood showed only traces of foreign albumin; titres in the other fœtal compartments were essentially unaffected. It is apparent that albumin, like antibodies, must to a large extent pass from the maternal into the fœtal blood via the vitelline vessels. On the other hand, the albumins can enter the exocoele and other compartments without the participation of a functional yolk-sac circulation. Direct passage into the exocoele is also supported by the observation that exocoele titres at one hour after injection were frequently higher than the blood titres, and in some instances the exocoele fluid was positive when the blood was still negative. The importance of the exocoele in the transfer of antibodies was indicated by the recent work of Brambell and Halliday[3] on the passage of anti-*Salmonella* into the rat fœtus close to term. These antibodies appear to pass successively from the uterine lumen into the exocoele, amniotic cavity, stomach and blood. Such a pathway, with the possible exception of entry into the blood, is consistent with our findings on the albumins in the 24–26 day rabbit fœtus, but not in the 19–21 day fœtus, in which the amniotic and stomach fluids showed no foreign protein or only traces at best. In both stages, however, the exocoele and the yolk-sac vessels seem to serve as primary reservoirs for the albumins taken up by the yolk sac.

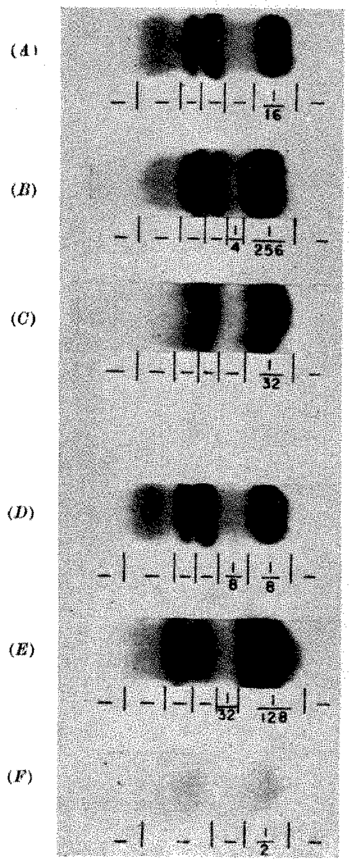

Fig. 1. Paper electrophoresis patterns of fluids from fœtal rabbits after injection of human or bovine serum albumins into pregnant females on the nineteenth or twenty-fourth days of gestation. Fractions under each pattern indicate titres for the foreign proteins, obtained from duplicate strips cut into segments (vertical lines). A dash indicates negative titre with fœtal fluid diluted 1/2. The volume of fœtal fluids subjected to electrophoresis and the proteins injected into the mother are: *A*, serum, 40 µl., human albumin, 24 days gestation; *B*, stomach contents, 100 µl., human albumin, 24 days gestation; *C*, exocoel fluid, 200 µl., human albumin, 19 days gestation; *D*, serum, 40 µl., bovine albumin, 24 days gestation; *E*, amniotic fluid, 100 µl., bovine albumin, 24 days gestation; *F*, allantoic fluid, 300 µl., bovine albumin, 24 days gestation

Antibody Production by Lymphocytes after *in vitro* Contact with Bacterial Antigen and Transfer to New-born Rabbits

There is as yet no direct evidence of antibody formation in lymphocytes. Neither descriptions of cytological changes of lymphocytes in lymphatic tissues during antibody production[1], nor the proof of release of γ-globulin from lymphoid cells[2], nor the demonstration of antibodies in tissue cultures of pure lymphocytes immunized *in vivo*[3] could reveal whether lymphocytes are producers or only carriers of antibodies. An attempt was made, therefore, to obtain antibody production after contact of lymphocytes from rabbit lymph with antigen *in vitro*.

We used the method of cell transfer to 2–5-day-old rabbits, which are not capable of active antibody response[4]. 2–4 ml. of lymph were collected under sterile conditions from the cisterna chyli of adult rabbits (1,500–3,000 gm.). With three exceptions, cells from each donor separately were washed three times with Hank's solution, suspended in 1–2 ml. of this solution and mixed with bacterial antigen (to *Brucella suis*, *Salmonella paratyphi B*) in the proportion of 2–6 microbes to each cell. 2×10^6 to 80×10^6 viable cells (according to the trypan-blue test) were injected intraperitoneally into each recipient. The differential counts of ethanol-fixed smears stained with methyl green–pyronine from thirteen donors showed the following estimate of the constitution of transferred lymph: blasts (probably lymphoblasts) 8·78 ± 0·95 per cent; prolymphocytes 17·41 ± 1·13 per cent; lymphocytes 72·59 ± 1·38 per cent; macrophages and monocytes 0·76 ± 0·22 per cent; granulocytes 0·46 ± 0·17 per cent. In five recipients splenectomy was performed 5 hr. before cell transfer.

In order to exclude possible participation of the recipient's tissues and to enable quantitative analysis of cell changes, in some cases the lymph cells in Hank's solution were transferred in diffusion chambers ('Plexiglass' cylinders with bases of 'Millipor' membranes of 0·8-μ porosity, content 0·4–0·6 ml.). These chambers were placed in the peritoneal cavity of recipient rabbits under ether anæsthesia.

New-born rabbits of the same litters served as controls. They received: (1) isolated spleen cells with antigen under the same conditions; (2) lymph cells without antigen; (3) cell-free lymph supernatant with antigen and (4) antigen alone in corresponding quantity. Thirty-two test animals and thirty-one controls from sixteen litters were used.

It was found that after transfer of lymph cells, antibodies appear in about 90 per cent of intact recipients (Table 1) after 2–4 days, the peak being attained after 5–8 days. There is a direct relation between the quantity of transferred cells and the antibody titre. Results on splenectomized animals suggest that, after direct injection of cells into the peritoneal cavity, antibody formation is due mainly to cells localized in the spleen. Cells in a diffusion chamber give relatively lower titres in the serum, but antibodies persist for a longer period and in higher titres inside the chamber (20 days, 1 : 16). Spleen-cell transfer results in 100 per cent antibody formation.

Other animals were examined histologically. Proliferation of the lymph cells injected directly occurs chiefly on the omentum and in the spleen within a few days. A prompt reaction of macrophages develops, together with granulation and fibrous tissue formation in the surrounding area. Clumps of immature and mature plasma cells and pyroninophil reticular cells are formed in the marginal zones of layers of transferred cells. The average spleen weight in test animals from the fifth to the twelfth day after transfer is 1·336 ± 0·104 gm./kgm. (ten rabbits), in controls with antigen only 0·939 ± 0·098 gm./kgm. (ten rabbits). In the chambers during the initial proliferation a rapid fall in the number of blast cells and shedding of cytoplasm of lymphocytes was observed. There is a definite increase in macrophages (22 per cent in 8 days), pyroninophil cells resembling reticular cells (up to 1·6 per cent), immature and mature plasma cells (up to 3·2 and 4 per cent in 4–8 days), cells crowded with Russel bodies and eosinophil crystals (up to 28·8 per cent in 8 days). In controls without antigen a slight degree of plasma cell development occurred. After 45 days, only macrophages and eosinophil crystals can be found in the chambers. Details will be given elsewhere.

Table 1

Mode of transfer	No. of cells ($\times 10^6$)	No. of recipients	Distribution of agglutinating titres						
			0	2	4	8	16	32	64
Lymph cells intraperitoneally	2–20	5	1	1	1	2	—	—	—
Lymph cells intraperitoneally	20–80	13	2	—	1	3	2	4	1
Lymph cells in diffusion chambers	2–20	9	—	—	4	2	3*	—	—
Lymph cells intraperitoneally after splenectomy	20–80	5	5	—	—	—	—	—	—
Spleen cells intraperitoneally	20–80	16	—	—	1	3	5	4	3
Lymph cells intraperitoneally without antigen	20–80	6	6	—	—	—	—	—	—
Antigen alone or with cell-free lymph supernatant	—	9	9	—	—	—	—	—	—

* 75×10^6 cells in two cases

It is concluded that lymphocytes from cisterna chyli can form antibodies after transfer to new-born animals, the metabolic change being connected or followed by morphological transformation of some of the less-mature cells into the macrophage and plasma-cell types which, however, may not be responsible for the amount of antibodies formed.

Surface Antigens of *Haemophilus pertussis*

It has been shown by Frappier and Guérault[1,2], and Frappier, Guérault and De Repentigny[3], that the antigen of *Haemophilus pertussis* which protects mice against intracerebral infection could be washed off the bacteria by saline (0·85 per cent sodium chloride). As this protective effect in the mouse is accepted as an indicator of the efficiency of vaccines in protecting children against whooping-cough it would appear that saline washings afford a ready means of obtaining the immunizing antigen of the organism free from the bulk of the bacterial cell. The washings were obtained from bacteria grown in a fluid medium, they were practically devoid of toxicity and stimulated agglutinin production in rabbits.

We have in general confirmed these findings using cultures from Bordet Gengou (*BG*) medium. Further observations showed that washings contained the histamine sensitizing factor of *H. pertussis* and that rabbit antiserum prepared against washings neutralized the histamine sensitizing factor and protected mice passively against intracerebral and intratracheal infection with *H. pertussis*.

The properties enumerated for washings were demonstrated also with an extract of *H. pertussis* obtained by treating the organisms with a mixture of solvents, consisting of thiourea, urea and formamide, according to a method employed by Dr. B. W. Lacey (personal communication). The extract so obtained had a high protective value for mice.

Extraction by a mixture of thiourea, urea and formamide removed more material than treatment with saline. The dry weight of the extract was greater than that for washings. Extracted bacteria were devoid of the histamine sensitizing factor whereas it was present in saline-washed bacteria. Although extracted bacteria still had agglutinogen and protected mice against intra-cerebral challenge, rabbit antiserum prepared against them was weak in passive protection of mice.

These findings raise the problem of the identity of the immunizing antigen of *H. pertussis* and its possible relationship with the histamine sensitizing factor or agglutinogen. The absence of the histamine sensitizing factor in extracted bacteria which retained their agglutinogen and their ability to protect mice (although probably somewhat reduced) might be interpreted as dissociating the antigen responsible for histamine sensitization from the agglutinogen and immunizing antigen. This may eventually be proved to be the case; but the result just noted could be due to differences in the threshold for detecting different biological effects rather than the operation of different entities.

We have found that serum from persons hyperimmunized with commercial pertussis vaccines contained anti-histamine sensitizing factor as well as agglutinin and mouse protective antibody.

For chemical examination of the antigens concerned it is desirable to prepare washings or extracts as free as possible from extraneous material. With *BG* medium bacterial growth was contaminated with antigenic material from the medium as was demonstrated by precipitin reaction in agar gel. This source of impurity was reduced by growing cultures on 'Cellophane' disks applied to the surface of *BG* medium, and this technique has been adopted throughout our investigations. In cultures grown on bare *BG* medium the histamine sensitizing factor diffused into the medium, but this was largely prevented by using 'Cellophane'. Bacteria grown on 'Cellophane', and washings from them, had more histamine sensitizing factor than was obtained from growth on the bare medium. Some mouse protective antigen escaped into the medium without 'Cellophane', and this too was avoided if 'Cellophane' was used, but the amount was not enough to make a detectable difference in the capacity of the bacteria to immunize mice against intracerebral challenge.

These findings suggest that the histamine sensitizing factor, agglutinogen and protective antigen may be surface components of the cell. Direct support for this view has been obtained by De Repentigny and Frappier[4], who found that fluorescent antibody against washings reacted with the surface of *H. pertussis* from liquid or solid media.

Examination of the washings by ultra-violet spectroscopy showed an absorption maximum at 265 mμ corresponding with nucleic acids or purine–pyrimidine constituents. These materials were removed by dialysis from the washings which then had an absorption spectrum similar to that of proteins. The dialysed washings retained their histamine sensitizing and mouse protective properties.

Paper chromatography of hydrolysates of the dialysed washings and extract showed an amino-acid composition typical of proteins. Glucosamine, often present in protein–lipid–carbohydrate complexes of bacterial origin was also found. Freeze-dried preparations gave a total nitrogen value of 9·5–14 per cent. Reducing substances accounted for 5–10 per cent of the weight of dialysed extract. Small amounts of glucose and galactose were detected. These results were consistent with the presence of a protein–lipid–carbohydrate complex in the dialysed washings or extract.

Antigenic Formulæ for the Genus *Clostridium*

ANTIGENIC formulæ for *Clostridium sporogenes*, *Clostridium histolyticum* and *Clostridium parabotulinum* were devised by Mandia and Bruner[1] and by Mandia[2–4]. These were restricted to the heat-labile antigens and excluded the *O*- and the spore- (*S*-) antigens.

It is, however, no longer possible to ignore the antigenicity of the spore which was demonstrated by Defalle[5] as early as 1902. Howie and Cruickshank[6] confirmed this antigenicity with a relatively pure suspension of *Cl. sporogenes*, and laid down the principles of setting separate spore and vegetative antigen–antibody systems.

These principles have been used for devising spore and vegetative agglutination and agglutinin-absorption tests, using 37 *Clostridium septicum* and 35 *Clostridium chauvoei* strains isolated in Britain, France and the United States. The two organisms appeared to share a common spore (*S*)-antigen, and no cross-agglutination occurred between their vegetative antigens. All *Cl. chauvoei* strains shared the same *O*-antigen, but possessed two different *H*-types. There was complete identity between the *O*-antigens of types I and III and types II and IV of *Cl. septicum*, and varying cross-agglutination, but no agglutinin-absorption, between their 5 *H*-types.

These results explain earlier contradicting reports on varying cross-agglutination between *Cl. septicum* and *Cl. chauvoei*. The antigenicity of the spore, previously attributed to the vegetative forms, no doubt depended on the degree of sporulation of the cultures and the methods used by the different workers in preparing the antigens. Fuerth[7] and Conradi and Bieling[8] have, however, described a 'spore' as well as a 'vegetative cycle' for *Cl. septicum* and *Cl. chauvoei*; and Kreuzer[9] affirmed the presence of a common heat-stable antigen between them.

I am of the opinion that all classification within the genus *Clostridium* should be firmly based on antigenic characters. These are the most reliable, and the more stable, of all the criteria we now possess. The use of antigenic formulæ comprising the *S*-, the *O*- and the *H*-antigens would simplify their identification, as well as overcome any difficulty of antigenic overlapping between the different species.

Similar investigations are now being made to extend the work to other *Clostridia*.

An Improved Technique for Spot Testing, using a 'Cellophane' Membrane

If the coloured compound in a spot test is allowed to form within a 'Cellophane' membrane instead of on filter paper, the colour can be seen much more clearly, and colour comparison is greatly facilitated. The procedure is described below for the formation of salicyloylhydrazones by aldehydes and ketones[1], but is of general application.

A test-tube containing a few drops of the carbonyl compound (if it is volatile) is covered with a sheet of 'Cellophane' previously moistened with 5 per cent aqueous acetic acid, and the 'Cellophane' is firmly secured with a rubber band. A drop of a saturated solution of salicyloylhydrazide in 5 per cent acetic acid is put on the 'Cellophane', through which it permeates to meet the carbonyl compound penetrating from the other side by volatilization. Interference from non-volatile substances is avoided, and, since the volatile substance is virtually sealed in, contamination of neighbouring tests is prevented. Excess reagent can be removed by simply wiping the outer surface of the 'Cellophane' with a damp cloth.

The method can be used for non-volatile substances, for example, oxosteroids, by placing a 5 per cent aqueous acetic acid solution of them in the 'Cellophane'-capped tube. The test-tube is inverted so that the lower surface of the 'Cellophane' is wetted, and a drop of reagent put on the top surface as before.

The new technique can be applied to all colour reactions which take place in aqueous solution. Non-waterproofed 'Cellophane' must, of course, be used.

Generation and Propagation of Impulses during Refractoriness in a Pacinian Corpuscle

Deformation of mechano-receptors gives rise to generator potentials which in turn eventually set up propagated potentials. In order to analyse generator potentials it is desirable to block the propagated potential. In the Pacinian corpuscle this may be done by the aid of drugs, by changing the ionic environment of the receptor[1] or, as here reported, by taking advantage of differences in duration of the refractory period of generator and propagated events. Generator potentials alone are obtained when the deformation of the receptor occurs during the refractory period of the propagated potential.

Pacinian corpuscles of the cat's mesentery were isolated, together with a length of afferent axon[2,3], and set up in a bath containing an oxygenated Krebs's solution covered with mineral oil. The electric activity of the sense organ was led off between the Krebs's–oil interface, serving as fluid electrode, and a platinum electrode placed on the axon at some distance from the corpuscle. For recording of generator potentials, the interface was adjusted to lay at the site of the axon's emergence from the corpuscle. Graduable mechanical stimuli were provided by the deflexions of a piezo-electric crystal, applied to the corpuscle by a glass stylus[3]. The stylus's movements were followed photo-electrically, and were found to follow up to 1,000 pulses/s. with fidelity.

When two mechanical stimuli of threshold strength are successively delivered to the corpuscle at an interval longer than 10 msec. (relative refractory period), each stimulus causes the firing of a propagated potential. Upon progressive reduction of stimulus interval the threshold for setting up a propagated response rises[3–5]. At the same time, the propagated potential falls gradually to 75 per cent of its resting magnitude, and finally becomes abruptly blocked within the corpuscle. A non-propagated all-or-nothing potential, presumably corresponding to activity of the first intracorpuscular node of Ranvier, is then detected. This potential declines gradually as the interval is progressively shortened, and finally vanishes leaving a graded potential (generator potential) as the only response to mechanical stimuli. This potential increases as a function of stimulus strength, without changes in latency.

A generator potential leaves a refractory state behind, so that the amplitude of a second generator potential falling on its refractory trail is directly related to the time elapsed after the first. Unlike the propagated potential, the generator potential decreases gradually to zero as the stimulus interval is progressively shortened, revealing no sign of absolute refractoriness. Furthermore, the amplitude of a refractory generator potential is inversely related to the magnitude of the preceding generator response[1]. However, the size of the generator potential is independent of the refractory state left by a preceding propagated potential. For example, the amplitude of a generator potential in response to the second stimulus belonging to a pair of stimuli, remains the same whether preceded by a generator potential or a four times greater propagated potential. Had the latter been an equally large generator potential, the second generator potential would have become considerably reduced. This independence between generator and propagated events may be regarded as a further argument for spatial and functional differences in their origin[4,6].

For a given stimulus interval the minimal amplitude of generator potential at which firing of propagated potentials occurs (firing height) is fairly constant. The firing height increases progressively as the interval is shortened during the relative refractory period. The increase in firing height and the reduction in amplitude of the refractory generator potential determine the threshold rise during the corpuscle's relative refractory period.

The generator potential set up in response to a single mechanical stimulus decays to zero in 4–8 msec. The decay time is constant for a given receptor and is independent of duration of stimulus. However, the spontaneous decay of generator potential is not due to the receptor's incapacity for sustaining a generator potential, since with repetitive mechanical stimulation of the corpuscle at, for example, the rate of 900 stimuli per second a generator potential is built up which shows no decline over 100 msec. of observation. A mechanical component in adaptation[7] may account for the spontaneous decline in generator response.

This work was aided by a grant from the Rockefeller Foundation.

Variations in Axonal Diameters of Myelinated Nerve Fibres: Apparent or Real?

IN a paper read to the Anatomical Society of Great Britain and Ireland on November 29, Miss B. Higgs, of the Royal Free Hospital School of Medicine, put forward clear evidence that fixatives may affect the relative diameters of a nerve fibre in the nodal and internodal regions. Although readily accepting her findings, which provide at least a partial explanation for the differences in axonal diameters seen in fixed material, it is obvious that such a fixation artefact cannot explain the apparent diameter variations recorded as existing in living nerve fibres by de Renyi (1929).

It had occurred to me that the highly refractile myelin sheath might act as a lens and magnify the internodal portions of axon, making them seem abnormally wide in comparison with the uncovered axon in the nodal regions. To illustrate this point, on the same day I showed to the Society a lantern slide depicting a simple piece of apparatus which I had made. This consisted of a black rod (axon) partially enclosed in a water-filled glass tube (myelin sheath). The enclosed portion of rod presented a diameter some 30 per cent greater than the un-enclosed portions (Fig. 1). It may well be that a myelin sheath would indeed act in this way in living tissue, and it is possible that 'fixed' myelin may have an even higher refractive index and produce even greater magnification of the internodal portions of the axon.

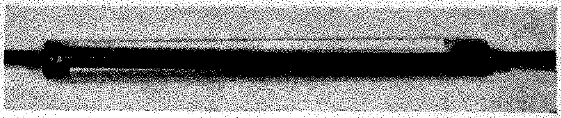

Fig. 1

Since nerves are extensile structures then they must possess the ability to recoil. This property may be invested, in part at least, in the myelin sheath; and, in teased preparations, the myelin sheaths, by virtue of this recoil mechanism, may cause actual shortening and broadening of the internodal axoplasm without exerting a similar effect on the nodal axoplasm.

Dec. 9.

QUANTITATIVE histological methods are employed in the study of the myelinated fibre population of peripheral nerve and frequently a histogram is constructed to demonstrate the myelinated fibre diameter size frequency distribution. For this purpose fibres are grouped according to calibre, based upon measurements of diameter of the whole fibre, including the myelin sheath. Within any fibre group the relation of the axonal diameter to that of the total fibre is thought to be relatively constant. Thus, for fibres of 10–12μ, the proportion of axonal to external diameter is usually considered to be 0·7 : 1. This ratio was obtained by Donaldson and Hoke[1], and later workers[2,3], using stained transverse sections of fixed nerve, and by de Rényi[4] using intact, unfixed fibres. The results of both these techniques need correction, the former for distortion inherent in the fixation and subsequent processing, and the latter for optical effects.

When fresh teased preparations of peripheral nerve are examined microscopically, measurements of axon diameter are affected by the optical properties of the highly refractile myelin sheath and of the immersion medium. At the mid-internodal region the basic problem is that of an axon within a cylindrical convex lens of myelin surrounded by immersion fluid. The interfaces to be considered are: (i) myelin – immersion medium; and (ii) immersion medium – air.

Experiments were conducted using normal saline as the immersion fluid and lecithin as the lens matrix, the optical properties of lecithin being comparable to those of the myelin sheath[5]. Determinations of the individual refractive indices of these media gave the following values for the effective indices operative at the interfaces when considering an emergent beam: interface i, 0·89; interface ii, 0·75.

Sample measurements made on a preparation of mammalian nerve teased in normal saline: external diameter, 11μ; apparent axon diameter, 8μ. The receiving angle of the objective used, under the conditions of the experiment, was 45°. Theoretical consideration of the myelin lens system and the appropriate refractive indices, involving the construction of scale diagrams, showed that the virtual images produced by the axonal margin lie on a curve. If the most lateral point on this curve is considered, the magnification of the system is 20 per cent. Thus the corrected value for the axon diameter would theoretically be 6·7μ and the ratio of the axonal to the external diameter, 0·6 : 1. However, experiments in which nerve fibres were immersed in fluids of different refractive indices suggest that the refractive index of myelin considered in relation to a radial optic axis is rather higher than that of lecithin, and therefore the corrected ratio would be even lower.

This low ratio, at variance with that obtained for fibres of similar size in fixed preparations, receives confirmation from the work of one of us (P. L. W.). Measurements of axonal and external diameter have been made using thin transverse sections of fresh, unfixed peripheral nerve. In such preparations, using orthodox forms of illumination, fibres in the range 10–12μ show a ratio of axonal to external diameter of 0·45–0·60 : 1 (mean 0·51 : 1). However, preliminary observations using interference and polarizing techniques indicate that even this ratio may need further reduction. Details of the technique used and full results will be published elsewhere.

The problem thus far has been simplified; it is in fact much more complex. The ultra-structure of myelin, and thus its optical properties, vary[5]. In addition one must consider the possible effects of the immersion medium on the properties of myelin[5,6]. The thickness of the myelin sheath varies not only with fibre diameter[2,3,7] but also in different regions of the same fibre. Differences in thickness and curvature are most obvious in the paranodal region[8].

It is hoped to evolve a correction factor of more general application.

L	'Guardian' relay, 5,000 ohms, 4 PDT	V_2	2*D*21	

During work on the relation of acetylcholine to nervous activity in insects[1,2] an apparatus was devised for the stimulation of the sensillæ of the cerci of *Periplaneta americana* L. by puffs of air. Since the apparatus allows separate control of strength, duration and frequency of the puffs of air, it is felt that it might find applications in other problems. The apparatus consists of an electronic switch controlling a solenoid valve through which compressed air is led to the point of application. A pressure regulator in the air line determines the strength of the puffs of air, while the duration and frequency are determined by the electronic switch. The operation of the electronic switch (Fig. 1) is as follows. Firing of the thyratron V_2 causes a surge of current through the relay L, depressing the three contacts. This activates the solenoid valve, charges condenser C_2, cuts out V_2 and allows C_5 (or C_4 or C_6, according to the setting of S_2) to discharge through L. The relay armature remains in this position for a period determined by the LC_5 time-constant and then returns to its normal or upper position, closing the solenoid valve, recharging C_5 and reconnecting V_2. The voltage on C_2 now leaks off through R_3, R_4, P and L, producing a slowly decaying bias on V_2 (which may be altered by the setting on P) until V_2 again fires, repeating the cycle. Thus the setting on P determines the time during which the solenoid valve is closed, while the capacity of the condenser selected by S_2 determines how long it is open. The potentiometer P provides intervals from 0·45–8·0 sec., the calibrated scale being slightly expanded in the lower range, while with S_2 times of 0·13, 0·25 and 0·56 sec. were obtained. Other time-intervals are possible by altering the capacity of condensers C_2 to C_6.

Smoother and quieter operation of the Skinner electric solenoid valve (supplied by Minneapolis-Honeywell Regulator Co., Philadelphia 4, Pennsylvania) results from the use of direct current supplied by the selenium rectifier *SR*. Noise from valve operation, which in itself causes sensory stimulation, is eliminated by encasing the valve assembly in a rubber-mounted wooden box lined with two inches of fibre glass.

In a typical experiment puffs of air were led by a plastic tube to a glass tip mounted behind the roach cerci. Nerve activity was recorded with a 'Tektronix' Type 512 oscilloscope and a 'Fairchild' camera. The control unit for the camera was activated through a fourth contact on relay L, thereby synchronizing the camera operation with a puff of air.

Silicate in the Metabolism of *Azotobacter vinelandii*

MOLYBDENUM complexed as silico-molybdate has been shown to be very active in the re-activation of aldehyde oxidase from which the molybdenum has been removed by dialysis[1]. Other reports have implicated silicate, phosphate and other anions as agents which increase the activity of molybdate-dependent enzymes[2,3]. Jacobs and Sanadi[4] suggested that a silico-molybdate complex was involved in a terminal electron transport system that was coupled with phosphorylation. It was shown by Glenn and Crane[5], however, that the *in vivo* functioning of aldehyde oxidase was probably not dependent on silico-molybdate even though it did greatly enhance the activity of the *in vitro* system.

It has already been shown that *A. vinelandii* is capable of incorporating into molybdo-protein as much as 100 times more molybdate than is required for optimum rate of growth[6].

We were led to consider the possible relationship of silicate and molybdate in the metabolism of *Azotobacter* by the observation that 100 p.p.m. germanium (as germanate) inhibits the growth of *Azotobacter* by 30–50 per cent. Because germanium is in the same chemical group as silicon it seemed possible that germanium was acting as an inhibitor of a silicate function much as tungstate inhibits molybdate function[6].

We therefore measured the uptake of silicate directly by the use of silicon-31 prepared from reagent grade silica gel (Mallinckrodt) by neutron bombardment. (Reactor facilities were provided by the Battelle Memorial Institute.) The irradiated silicon-31 was fused with sodium carbonate in a platinum crucible according to standard methods[7,8]. Half-life determinations showed the material to be about 99·9 per cent radiochemically pure.

Under culture conditions (in Burk's[9] nitrogen-free medium) such that *A. vinelandii* cells would take up nearly all the 1 p.p.m. molybdenum added to the culture, only 0·2 p.p.m. silicon-31 was taken up and only one-fourth of this was retained when the whole cells were washed thoroughly. When the molybdate-level of the medium was decreased so that the quantity of molybdate taken up decreased by a factor of 100, there was no change in the uptake of silicon-31. Furthermore, germanium at a level of 100 p.p.m. had no influence on the uptake of silicon-31, or molybdenum-99. Silicate concentrations also had no effect on the uptake of molybdenum-99.

The distribution of the silicon-31 retained by the cells in centrifugal fractions of these cells after sonic disruption was examined. In contrast to the published[10] distribution of molybdenum, in which both the highest total (more than 65 per cent) and highest specific activity of molybdenum-99 are found in a fraction sedimentable at 144,000*g*, only 5 per cent of the retained silicon-31 was found in the corresponding sedimentable fraction. The supernatant fraction contained 85 per cent of the total silicon-31, and the specific activity was 3½ times greater in the supernatant fraction than in any other.

As a result of the lack of correlation between the behaviour of silicon-31 and molybdenum-99 in these uptake and distribution studies in *Azotobacter vinelandii*, it is concluded that silicate is not involved in the molybdate metabolism of these cells as a silico-molybdate complex anion. Further, even though germanate does inhibit the growth of *Azotobacter*, it has no effect on the uptake of silicate.

Absorption and Distribution in Rats of Radioactive Phosphorus biologically incorporated in Food

IN this investigation absorption and distribution of phosphorus-32, biologically incorporated into fish muscle and bean leaves, was compared with its absorption after feeding as inorganic phosphate. Within limits of error, no differences were detected.

The experimental animals were 179 young adult female Sprague–Dawley rats (wt.-range 190–304 gm.: mean wt. 238 gm.) maintained *ad lib.* upon a Purina Lab Chow diet. The following solutions and suspensions containing radioactive phosphorus were administered orally to these animals:

(1) *Inorganic phosphorus*: 100 rats received 1 ml. of a *p*H 2 solution containing 25 μc. phosphorus-32 ($Na_2H^{32}PO_4$) and less than 0·6 μgm. of non-radioactive sodium hydrogen phosphate.

(2) *Fish protein phosphorus*: 51 rats received 2 ml. of a water/whitefish muscle homogenate (1/1, w/w) which had a concentration of a 0·5 μc. phosphorus-32 per ml. The muscles were derived from a fish which 72 hr. previously had received an intraperitoneal injection of 10 mc. of inorganic phosphorus-32.

(3) *Plant leaf phosphorus*: 28 rats received 1 ml. of a water/bean leaf homogenate (1/1, w/w), which contained 3·3 μc. phosphorus-32 per ml. It was prepared from leaves of young red kidney bean plants grown in an appropriate nutrient culture medium containing radioactive phosphorus-32.

Excreta were collected individually from each of eight animals of the inorganic phosphorus-32 group over a period of 40 days following the feeding. In the other two experimental groups, excreta were collected from each of eight animals up to 20 days following feeding.

The experimental animals were killed in groups of four at time-intervals ranging from 3 hr. to 40 days following radioisotope administration. The concentrations of phosphorus-32 in aliquots of blood, femur, liver, and excreta were determined. In order to measure the overall distribution of phosphorus-32 and total inert phosphorus[2] in the entire skeleton and teeth, a $Na_2H^{32}PO_4$ solution was orally administered to 17 additional young female rats. Three of these

Table 1. DISTRIBUTION OF PHOSPHORUS-32 FOLLOWING ORAL ADMINISTRATION

Tissue / Day	Administered dose/tissue (per cent)

1	0·7	3·6	28·2	6·9
5	0·3	1·7	36·0	12·8
10	0·2	0·9	39·8	15·6
20	0·1	0·4	43·6	18·7
40	0·1	0·1	46·9	21·7

* Total blood percentages are calculated on the basis of total rat blood volume of 5 per cent body-weight.

† Excreta are cumulative totals through experimental day indicated.

animals were killed at 6 days, and fourteen were killed 12 days after the feeding. These time differences did not appear to influence the phosphorus-32 concentrations of bones and teeth.

Although statistical analysis of the radioactivity values, corrected for decay and self-absorption, showed significant differences between groups of rats fed radioactivity from the same food source, none could be assigned to the effects of the radioactive food source itself. Real differences among results obtained from animals receiving the same treatment may have masked inter-treatment differences for the intra-treatment variations appeared to be related to the time when the experiments were performed. The lack of any effects ascribable to differences in the food forms in which phosphorus-32 was fed strongly suggests that phosphorus derived from animal or plant sources is absorbed and utilized very similarly to phosphate ion. For this reason results from each feeding group were combined and are summarized in Table 1. After the first ten days of the experimental period the rate of excretion of phosphorus-32 in fæces was equal to that in urine. Assuming that this equality was closely related to excretion of *absorbed* phosphorus-32 the earlier excess of phosphorus-32 in fæces, as compared to urine, was taken as the *unabsorbed* fraction of the fed dose. On this basis about 75 per cent of the administered phosphorus-32 was absorbed—a confirmation of results of other investigations[3]. Table 1 shows that by the tenth day more than 95 per cent of the unabsorbed phosphorus-32 had appeared in the fæces, while a combined total of more than 50 per cent of the total fed was excreted in urine and fæces together.

No statistically significant changes with time in deposition and retention of phosphorus-32 by bones and teeth were found, and mean values are summarized in Table 2. The total skeletal concentration of phosphorus-32 was 13·5 per cent of the administered dose, a value from 40 per cent to 70 per cent less than those reported previously[3–5]. Comparison of the total skeletal phosphorus-32 to the phosphorus-32 content of the relatively accessible femur yields a factor of 24·6 ± 1·2. The mean concentration of phosphorus-32 in bone was more than twice that of the molar teeth, but less than a third that of the incisors. The average of 10·8 per cent stable phosphorus-31 in bone is considerably higher than the 8 per cent reported for rat bone in a previous study[6], but is close to a 10·4 per cent reported for human bone[7]. The non-radioactive phosphorus content of the teeth types was higher than the bone value, but accords with the 13 per cent reported previously for rat incisor[8], and is also within the range of values reported for human enamel and dentin[7]. These differences between bone and tooth concentrations of phosphorus-32 and phosphorus-31, reflected in their phosphorus-32/phosphorus-31 ratios, may be accounted for by differences in growth-rates of these tissues[9].

Table 2. DISTRIBUTION OF PHOSPHORUS IN BONE AND TEETH

Tissue / Isotope	Bone*	Molars	Incisors
Phosphorus-32 (per cent dose/gm.)	0·9 ± 0·05†	0·4 ± 0·1	3·4 ± 1·0
Phosphorus-31 (gm./100 gm.)	10·8 ± 0·6	13·3 ± 0·9	13·5 ± 1·2
Phosphorus-32/phosphorus-31 (per cent dose/gm.)	8·3 ± 0·04	3·0 ± 0·6	25·2 ± 6·7

* Total phosphorus-32 of skeleton amounted to 13·5 per cent of administered dose. Femur contained a total of 0·55 ± 0·04 per cent of dose.

† Values are means ± standard deviation.

We gratefully acknowledge our debt to J. H. Rediske and R. C. Pendleton for supplying the phosphorus-32 labelled bean leaves and whitefish muscle; to Joan Hess, Alma Crosby, and members of the Biology Control Operation for skilled technical assistance; and to H. T. Norton and D. W. Gaylor for statistical analysis of the experimental results.

This paper is based on work performed under Contract No. *W*–31–109–Eng–52 for the Atomic Energy Commission. Portions of it were presented at the meetings of the Pacific Slope Biochemical Conference, Seattle, Washington, June 12, 1956. The radioactive phosphorus used in this investigation was obtained on allocation from the Isotopes Division, United States Atomic Energy Commission.

Hydrogen Peroxide and Tumour Therapy

TEN rats were implanted with Walker tumour and on the same day and succeeding days of the experiment the drinking water was replaced by 0·45 per cent hydrogen peroxide as described by Holman[1]. They all died at the same time (13–14 days) with tumours of the same weight (25–34 gm.) as in the ten control rats. Another transplantable tumour, the Sheffield *Rd*/3 sarcoma, was also used in an exactly similar experiment except that there were 6 rats per group. In the peroxide group all died at 16–21 days (tumour-weight 38–46 gm.) and in the control group receiving tap water there was one natural regression and the remaining 5 died at 16–21 days (tumour-weight 32–39 gm.). We have had a long experience with the actions of possible chemotherapeutic agents on these tumours, and they are responsive to some of them. We can assert confidently that in the environment of the University of Sheffield Field Laboratories this particular treatment is completely ineffective.

Much earlier experiments, made for other reasons, in which spontaneous and transplanted tumours were injected intratumorally with various concentrations of commercial hydrogen peroxide at intervals from an early stage of growth, were all essentially negative.

Holman makes no reference to the behaviour of his tumour when implanted into control untreated rats. From our own experience we know that even normally highly transplantable tumours occasionally pass through phases when the incidence of natural tumour regression is substantial. In view of this we feel that the 'cures' obtained by Holman may have been, in fact, natural tumour regressions.

Development of Eggs before the Final Moult in *Pratylenchus*

Among nematodes separated from soil about the roots of Grenache vines in February 1957 were females of *Pratylenchus* which carried eggs at their tails, outside the body but within a partly cast cuticle. Six specimens were recovered from a few pounds of soil. The life-cycle of a typical *Pratylenchus*[1] includes four moults from egg to adult, the first moult occurring in the egg, where the second-stage larva may be distinguished by the appearance of a well-defined buccal spear. In each of these specimens the egg contained a clearly differentiated second-stage larva. The cuticle of the nematode was detached at the head region and at the rear of the body from a point anterior to the vulva. Many normal specimens of *Pratylenchus* were also present, and one apparently larval female carried an egg with a second-stage larva in the oviduct.

Three of the specimens with eggs at the tail were kept in a dish of water. Two died within a few days, but the third emerged about half-way from the old cuticle before death.

Ten similar specimens were recovered from samples taken at the same site about a month later. One of these carried two fully differentiated eggs within the old cuticle. Two specimens showed no differentiation in the eggs—just a number of cells. All showed displacement of the cephalic cap, which indicated commencement of moulting. One specimen which started to emerge from the old cuticle was transferred to a slide, and under the slight pressure of the cover-glass the nematode completed the moult in a few minutes, surviving for about a week on the slide. The egg with cast cuticle was retained for more than a fortnight in water, but did not hatch.

It appears that females of this species may, in certain circumstances, produce eggs before the final moult takes place. Eggs thus produced cannot be laid in the normal way as there is no adequate aperture at the vulva for them to pass the larval cuticle. The eggs are retained in the body, and may undergo considerable development, until the final moult commences. When the cuticle begins to separate from the body, the egg can pass the vulva, and finds its way to the tail within the cuticular sac. Completion of moulting releases the egg. Although the one egg obtained free from these specimens did not hatch, these eggs may normally be viable. However, the fact that so many of the eggs observed were at an advanced stage of development suggests perhaps that hatching has been inhibited.

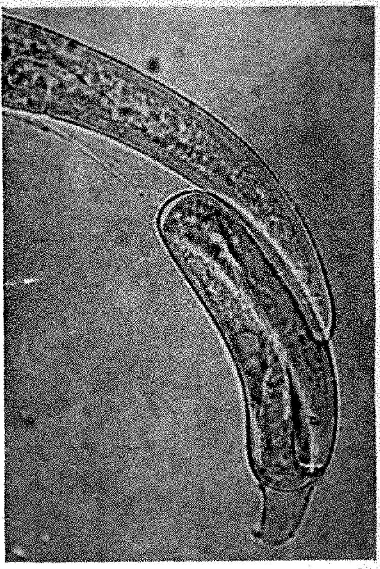

Fig. 1. Tail of *Pratylenchus minyus* showing egg retained by partly cast cuticle

Little is known of the mechanisms which control development in plant parasitic nematodes. It cannot be judged whether development of the reproductive system has been accelerated, or whether moulting has been retarded in these specimens, but the two processes are obviously not interdependent. No treatment other than normal vineyard practice has been applied to the area from which these nematodes were taken.

The species concerned is morphologically similar to *Pratylenchus minyus* Sher and Allen[2], but no males have been found.

Light Reactions of Littoral Gastropods

Molluscan behaviour has attracted the attention of many workers, and the literature contains several references to the homing ability and direction finding in various gastropods[1]. Light is acknowledged as an important factor in such mechanisms in numerous invertebrates, and recently the plane of polarization of light has been shown to be an operative factor in the orientation of *Eupagurus bernhardus*[2], the xiphosuran *Limulus*[3], some hymenopterous and lepidopterous larvæ[4], and various insects[5].

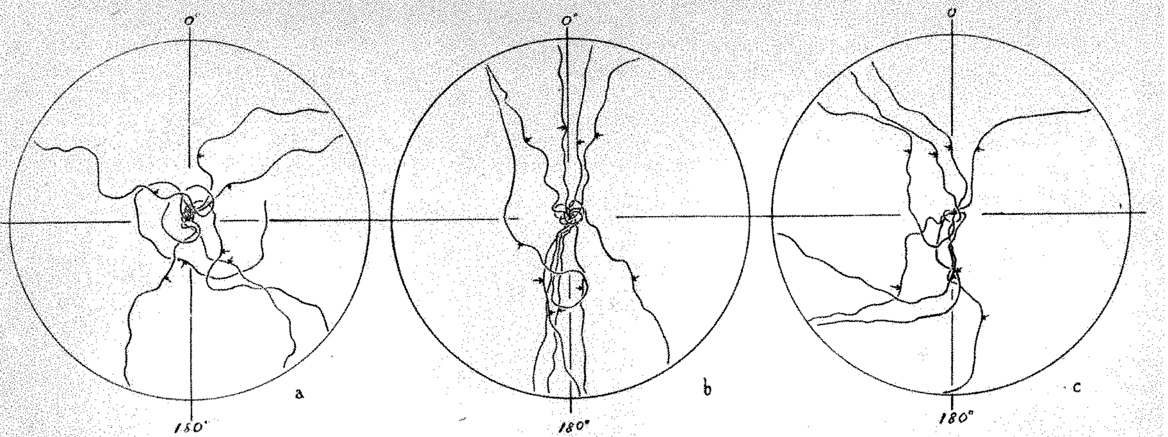

Fig. 1. Tracks under sea water: (*a*) non-polarized light, ← rotation of 'Polaroid' holder; (*b*) polarized light, 'Polaroid' momentarily turned through 90° and back again, ← rotation of 'Polaroid'; (*c*) polarized light, 'Polaroid' turned through 90° and left there, ← rotation of 'Polaroid'

During an investigation of the behaviour of several species of *Littorina* to various stimuli, it was found that *Littorina littoralis* (L.) (=*obtusata*) gave a very strong light compass reaction. This species was then tested with plane polarized light as follows. A disk of 'Polaroid' some 4 in. in diameter was mounted in front of a 500-W. source of light fitted with a heat filter. The whole apparatus was aligned with the optical axis vertical to the plane upon which individual specimens of *Littorina* were allowed to crawl. The plane of polarization was freely adjustable by rotation of the 'Polaroid' disk. Experiments were carried out on more than 150 specimens moving in air and under water. The track of each specimen was plotted as it moved, so that all its movements from the instant of illumination were recorded.

Three experimental conditions were applied: (*a*) The plane of polarization of the light was maintained along the reference axis. After the animal had traversed a standard distance from the starting point, the plane of polarization was momentarily rotated through 90° and returned to its original direction; (*b*) the plane of polarization was rotated through 90° from the reference axis after the animal had traversed the standard distance, and left in its new position; (*c*) the same as for (*a*) and (*b*) but with non-polarized light.

Fig. 1, *a–c*, shows a random selection of tracks obtained under water by the above treatments. A comparable series was obtained in air.

The results are summarized in Tables 1 and 2. All the angles indicated are angles of deviation of the tracks from the reference axis. These results were shown to be highly significant by the χ^2 test and prove that *L. littoralis* orientates itself along the plane of polarization of light falling on it from above.

Further experiments are planned to investigate how the eye detects the plane of polarization of light

Neuro-Anatomical Site in Tick Paralysis

Previous studies[1] have shown that tick paralysis, induced in mongrel dogs by applying the wood tick *Dermacentor andersoni* Stiles, is due to failure in transmission at the neuro-muscular junction because: (*a*) the anterior tibial muscle in a paralysed dog responded to direct but not to indirect stimulation through the peroneal nerve; (*b*) the motor nerve fibres conducted an impulse.

More recent investigations have demonstrated the following: The muscle contracts on rapid close intra-arterial injections of acetylcholine; neostigmine does not facilitate transmission in a fully paralysed muscle and causes only a slight improvement in a partially paralysed one; neither cathodal nor anodal current facilitate transmission in a fully paralysed muscle; the paralysis is intensified by curare, but is uninfluenced by pentamethonium; tetanization via the nerve slightly facilitates transmission of subsequent individual pulses in both the partially and completely paralysed muscle and in the former the tetanus is well maintained. These results indicate that the neuro-muscular block is dissimilar to that produced by the competitive and depolarizing blocking agents and anticholinesterases.

Functional activity of the end-plates is indicated by (*a*) contraction of the muscle on close intra-arterial injection of acetylcholine, (*b*) their depolarization by succinylcholine.

Table 1 shows the response of the normal, partially and completely paralysed anterior tibial muscle to close intra-arterial injections of acetylcholine. Increasing paralysis apparently produces an increasing sensitivity of the muscle to acetylcholine, the paralysed muscle behaving like a denervated one.

End-plates could be located in the paralysed anterior tibial muscle by sweeping its undersurface with a wick electrode after an injection of succinylcholine, the technique being similar to that described by Burns and Paton[2]. Usually four or more end-plate regions could be located in this way. The depolarizing effect of the succinylcholine was then permitted to wear off. In an apparently paralysed muscle, usually one or more muscle fibres contracted on nerve stimulation and the site of minimum latency of the action potential corresponded to only one of the located end-plate regions. Neither action nor end-plate potentials could be detected at the other located end-plate regions. The findings suggest that the probable mechanism for the paralysis is due to failure in the liberation or synthesis of acetylcholine at the nerve terminals.

Table 1. Sensitivity of Anterior Tibial Muscle to Rapid Close Intra-arterial Injection of Acetylcholine

Anterior tibial muscle	No. of experiments	Approximate average dose (μgm.) of acetylcholine to produce	
		Threshold contraction	Contraction = maximal muscle twitch
Normal	4	5	50
Partially paralysed	3	1	·15
Fully paralysed	1	?	1

In an attempt to localize exactly the site of the neuro-muscular block, the anterior tibial muscle was stimulated directly in a completely paralysed animal before and after the administration of curare. No difference could be detected in the magnitude of the mechanical responses indicating that the block is probably located at the nerve terminals in contradistinction to that in botulism poisoning, where the block is evidently proximal to the terminals[3].

The only effective method, known to date, of producing tick paralysis is by applying the wild ticks. When a saline extract (1 gm./ml.) of 128 engorged female ticks removed from paralysed dogs was injected intra-arterially (3 ml. × 1 ml.) and intravenously (1, 10 and 10 ml.) into a normal anæsthetized dog, it produced no detectable effect on the mechanical response of the anterior tibial muscle during indirect stimulation. Evidently continuous secretion of a 'toxin' by the ticks is necessary to produce paralysis because rapid recovery occurs on removal of the ticks.

As the tick 'toxin' appears to interfere with the liberation of acetylcholine at the neuro-muscular junction, one might expect that it would also interfere with acetylcholine liberation at other sites, for example, ganglionic and neuro-effector cholinergic junctions. Stimulation of the central end of the cervical sympathetic, proximal to the superior cervical ganglion, resulted in a normal dilation of the pupil and retraction of the nictitating membrane in a paralysed dog and stimulation of the peripheral end of the vagus in the neck caused normal cardiac slowing. In addition, if acetylcholine liberation in sympathetic ganglia was diminished in a paralysed animal one might expect to find a low blood pressure. The blood pressure in five paralysed dogs were within normal limits (130, 150, 100, 170 and 190 mm. mercury). Evidently the tick 'toxin' exhibits a specific predilection for the neuro-muscular junction.

This study was aided by a grant from the Department of Agriculture, Ottawa, Canada.

Anthocyanins in Blackcurrant Fruits

Robinson and Robinson[1] investigated the anthocyanin pigments of the fruit of the blackcurrant (*Ribes nigrum*) and stated that the skins contained a cyanidin-3-bioside. Cyanidin was the only aglycone found; but it was thought possible that small amounts of delphinidin were present. Fouassin[2] has recently examined blackcurrant pigments by paper

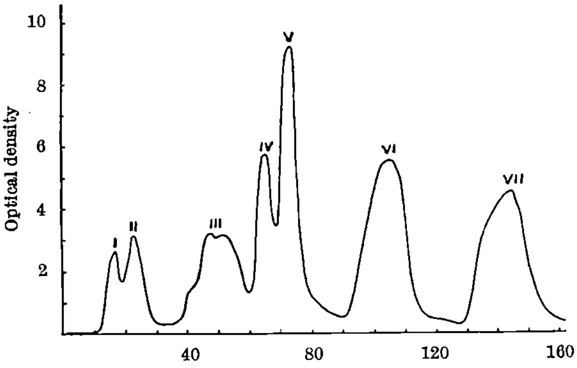

Fig. 1. Optical density at 545 mμ of blackcurrant anthocyanins eluted from a cellulose column

chromatography and has found two glycosides of cyanidin and two glycosides of delphinidin.

In the present investigations, extracts of blackcurrants in methanol containing 1 per cent hydrochloric acid have been shown to contain seven pigments, separable by cellulose column chromatography, using the organic phase of butanol/2*N* hydrochloric acid (1 : 1) as solvent. Whatman standard-grade cellulose powder, sieved to obtain the fraction larger than 200-mesh and smaller than 100-mesh, was packed in the solvent to give a column 50 × 4·4 cm., using a stainless-steel tamper to ensure even packing. The crude anthocyanin, approximately 0·7 gm., precipitated by ether from the methanolic extract, was dissolved in 40 ml. of the solvent, and this concentrated solution fed to the top of the column. The eluate was collected automatically in 10 ml. fractions. The graph of optical density at 545 mμ plotted against the tube number (Fig. 1) shows the presence of seven distinct bands.

To concentrate the slower-running bands (Fig. 1, IV, V, VI and VII), each eluate was mixed with an equal volume of acetone and adsorbed on to another cellulose column. The original solvent was washed off with acetone and the anthocyanins eluted with 0·1 per cent methanolic hydrochloric acid which was then readily removed under vacuum. The faster-running bands (Fig. 1, I, II and III) were not held tenaciously enough by the column to permit this procedure. Therefore, basic lead acetate was added to each eluate to form the lead complex which was then decomposed with methanolic hydrochloric acid and the solution filtered and evaporated to dryness. The residues were dissolved in 1 per cent hydrochloric acid and concentrated hydrochloric acid was added to make the final concentration 20 per cent. The solutions were stored in the refrigerator, and after several days the precipitated pigments were recovered.

Band I appeared on the column as a brownish front to band II, and it is considered to be a degradation product. The other bands fell into two groups of three on the basis of visual colour, bands II, IV and V being scarlet and bands III, VI and VII crimson. By comparison with known samples on paper chromatograms it was found that the material from band II was cyanidin, and the anthocyanins from bands IV and V yielded cyanidin on hydrolysis. Similarly, band III was found to be due to delphinidin and bands VI and VII to delphinidin glycosides.

After hydrolysis of the mixed anthocyanins from blackcurrants, glucose was the only sugar detected by paper chromatography. The anthocyanin from band V was shown to be chromatographically identical with chrysanthemin (cyanidin-3-glucoside) isolated from the petals of mauve chrysanthemums[3] and purified by passage through the cellulose column. The other cyanidin glucoside from band IV, after partial hydrolysis by boiling in 5 per cent hydrochloric acid for 30 min., was converted to a pigment chromatographically identical with chrysanthemin. Since a test[1] for acyl groups was negative it appears that the anthocyanin from band IV is a cyanidin diglucoside, possibly a 3-bioside as proposed by Robinson and Robinson[1] or the 3,5-diglucoside although its R_F values (Table 1) do not agree with those given by Bate-Smith[4].

Table 1. R_F VALUES OF BLACKCURRANT PIGMENTS

Band	Solvent system			
	Butanol/acetic acid/water (ref. 4)	Butanol/2 *N* hydrogen chloride (ref. 4)	*m*-Cresol/acetic acid/water (ref. 4)	Forrestal solvent (ref. 5)
II	Fades	0·74	Fades	0·47
III	Fades	0·44	Fades	0·30
IV	0·38	0·31	0·38	0·75
V	0·40	0·28	0·47	0·71
VI	0·25	0·19	0·14	0·67
VII	0·18	0·14	0·17	0·62

Partial hydrolysis of the delphinidin glucoside from band VI converted it into an anthocyanin identical with that from band VII. The R_F values (Table 1) of these two anthocyanins do not correspond with published values[4], but it is probable that they are a mono- and di-glucoside respectively of delphinidin. It is hoped to confirm the structure of these glucosides and the cyanidin diglucoside by synthesis.

Selective Uptake of Radiochemical Impurities by Mitochondria

WHEN using potassium-42 to trace the exchange of potassium in a suspension of non-metabolizing mitochondria from rat liver, specimens were obtained in which the specific activity of mitochondrial potassium appeared greater than the specific activity of the separated labelling medium. The radioactive material used was spectroscopically pure $^{42}K_2CO_3$, which had been irradiated for one week at the Atomic

Table 1

	Potassium (μequiv./ml.)	Radioactivity (counts/min./ml.)	Apparent specific activity (counts/min./μequiv.)
Suspending medium	136·5	$1·77 \times 10^7$	$1·30 \times 10^5$
Washed mitochondria	0·098	$1·92 \times 10^4$	$1·96 \times 10^5$

Mitochondria were prepared by differential centrifugation in 0·25 *M* sucrose + 0·025 *M tris* buffer at *p*H 7·0. After suspension in 0·15 *M* KCl + ^{42}K for 60 min. at 0° C., mitochondria were washed three times with sucrose-*tris*.

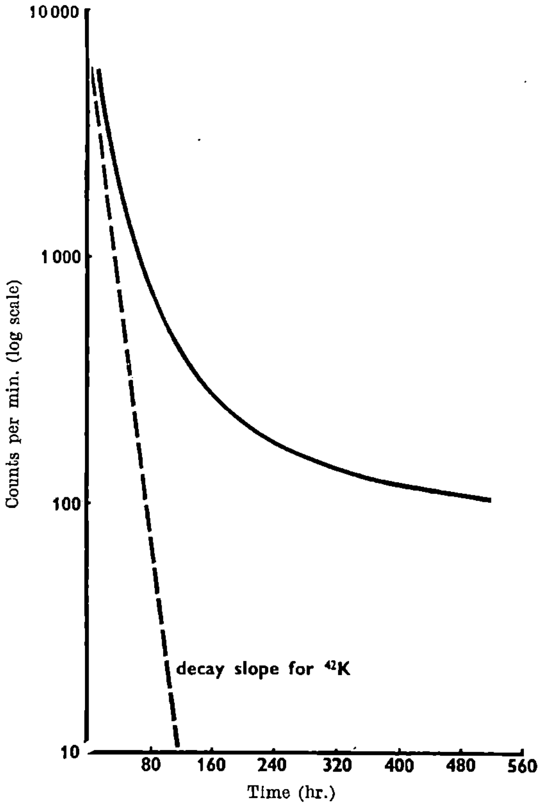

Fig. 1. The unbroken line represents the radioactive decay of the contaminants 'bound' to the mitochondria

Energy Research Establishment, Harwell. When measured on a *M*6 ('20th Century Electronics') Geiger–Müller counter, the apparent specific activity (counts/min./μequiv. potassium) of potassium on the labelled mitochondria was 1·5 times as great as that of potassium in the labelling solution (Table 1). On further investigation it was found that the decay of activity on the mitochondria corresponded to a half-life greater than 12·4 hr. (see Fig. 1).

The $^{42}K_2CO_3$ was found to contain several isotopes of half-life greater than 12·4 hr. The major contaminant has a half-life of approximately 30 hr. and occurs to the extent of 1 part in $2 \cdot 6 \times 10^4$ as measured by the *M*6-counter at the time of removal of the $^{42}K_2CO_3$ from the pile. Several other radioactive isotopes, of half-life between 10 and 25 days, were detected, and these amounted to 1 part in $6 \cdot 4 \times 10^5$. Slater[1] has shown that isolated muscle mitochondria have a high affinity for calcium: and the selective adsorption of the long-life isotopes by the liver mitochondria (Table 2) suggested that the contaminants were multivalent cations. This was confirmed by their behaviour on a column of cation exchange resin.

Table 2. RATIO OF POTASSIUM-42 TO RADIOACTIVE CONTAMINANTS

Suspending medium	10,000 : 1
Washed mitochondria	1 : 1

The available evidence strongly suggests that the contaminant of 30-hr. half-life is barium-135 and this should be removed from a solution of ^{42}KCl by adding barium chloride and a stoichiometric amount of sulphuric acid. This technique fails to remove other contaminants, and has the additional disadvantage of introducing trace amounts of Ba^{2+} (0·02 mequiv./l.) and SO_4^{2-} into the solution. A more satisfactory separation was achieved by eluting the potassium-42 from a cation exchange resin *IR* 120 (*K*) with 0·15 *M* potassium chloride.

A column (10 cm. × 1 cm.) of *IR* 120 (*H*) was treated with 20 ml. of 30 per cent potassium chloride (KCl) to convert it to the *K*-form. After washing with 200 ml. of distilled water, 60 ml. of 0·15 *M* ^{42}KCl was put down the column at 0·8 ml./min. The column was rewashed with 30 ml. of distilled water to remove anionic isotopes present and then treated with 300 ml. of 0·15 *M* potassium chloride solution. This brings off virtually all the potassium-42, and the most active fraction has about 70 per cent of the specific activity of the original material; 90 per cent of the original activity was recovered in 120 ml. of the eluate. Mitochondria labelled with this material showed no measurable deviation over a period of 40 hr. from the decay expected of potassium-42.

It is possible that biological material other than mitochondria may selectively accumulate substances present as impurities. The effect may be quite striking; in labelled mitochondria the ratio of contaminant to potassium-42 was ten thousand times greater than in the suspending medium. It is therefore desirable that radiochemical purity should be checked by observation of the labelled biological material itself and not merely of the original stock of radioisotope. This investigation was supported by the Endowment Fund of the Manchester Royal Infirmary and by the Rockefeller Foundation.

Some Effects of Carbon Dioxide-Bicarbonate Mixtures on the Oxidation and Reduction of Cytochrome c by *Ricinus* Mitochondria

THE observation that the succinic oxidase system of *Ricinus* mitochondria is inhibited by concentrations of carbon dioxide above about 20 per cent[1] has led us to investigate the effects of carbon dioxide on components of the respiratory chain.

Mitochondrial preparations from the endosperms of germinating castor oil beans[2] were diluted 8–10 times with ice-cold demineralized water and incubated at 0° for 30 min. to render the mitochondrial oxidase and reductase systems accessible to cytochrome *c*. In the resulting preparations the activities of succinic cytochrome *c* reductase, reduced diphosphopyridine nucleotide cytochrome *c* reductase and cytochrome *c* oxidase were determined by spectrophotometric measurement at 550 mμ of the oxidation and reduction of cytochrome *c*. The concentrations of carbon dioxide in the reaction mixtures were regulated[3] by the addition of the calculated amounts of a 0·32 *M* solution of sodium bicarbonate which had been equilibrated against a gas mixture containing 90 per cent carbon dioxide and 10 per cent oxygen at 25°, at which temperature all measurements were made. The *p*H of the carbon dioxide–bicarbonate mixture was 7·4. We shall refer the reaction rates simply to the carbon dioxide concentrations. This is convenient, since the results to be recorded may help to explain certain metabolic disturbances and growth responses of plant organs placed in atmospheres enriched with carbon dioxide. However, some of the effects may be due to the equilibrium concentration of bicarbonate ion.

For the measurement of succinic cytochrome *c* reductase activity, spectrophotometer cells contained 0·1 ml. of enzyme, 0·1 ml. of 2-amino-2-hydroxymethylpropane-1 : 3-diol (*tris*) buffer (20 per cent w/v, *p*H 7·4), 0·1 ml. of cytochrome *c* ($9{\cdot}4 \times 10^{-4}$ *M* in 1 per cent *tris* buffer, *p*H 7·4), 0·1 ml. of cyanide (2×10^{-3} *M*, *p*H 7·4), 0·05 ml. of succinate (1·2 *M*, *p*H 7·4), and the required amount of 90 per cent carbon dioxide–bicarbonate mixture in a total volume of 3 ml. The reaction was started by the addition of succinate. For the measurement of reduced diphosphopyridine nucleotide cytochrome *c* reductase, succinate was replaced by 0·05 ml. of reduced diphosphopyridine nucleotide ($8{\cdot}4 \times 10^{-3}$ *M*). For measurement of cytochrome *c* oxidase activity the reaction mixture was composed of 0·1 ml. of enzyme, 0·1 ml. of *tris* buffer, the required volume of 90 per cent carbon dioxide–bicarbonate mixture, and 0·2 ml. of reduced cytochrome *c* ($4{\cdot}7 \times 10^{-4}$ *M* in 1 per cent *tris* buffer) in a total volume of 3 ml. The reaction was started by the addition of reduced cytochrome *c*. Readings were taken at 15-sec. intervals for 2 min. It was not considered necessary to equilibrate the final reaction mixture with an atmosphere containing the appropriate concentration of carbon dioxide as it had been previously ascertained that for the short period of the experimental measurement the error resulting from the diffusion of carbon dioxide was negligible.

In Table 1 the rates of each of the three reactions studied at different concentrations of carbon dioxide are given as percentages of the rates in air. The control rates in air were 10·4 μmoles cytochrome *c* reduced/hr./gm. of fresh tissue for succinic cytochrome *c* reductase; 15·8 μmoles cytochrome *c* reduced/hr./gm. of fresh tissue for reduced diphosphophyridine nucleotide cytochrome *c* reductase; and for cytochrome *c* oxidase, *k* the first-order velocity constant, was 7·54/hr./gm. of fresh tissue. Cytochrome oxidase was stimulated at the lower concentrations of carbon dioxide, with a maximum rate at about 20 per cent carbon dioxide, and was inhibited at the higher concentrations. Using different experimental conditions, Miller and Evans[4] have examined the effects of bicarbonate on cytochrome oxidase of root mitochondria. They obtained similar results, although the stimulation at low concentrations was less marked. They found larger increases in rate with sodium chloride, nitrate or sulphate, which suggests that the stimulation at low bicarbonate (or carbon dioxide) concentrations is a non-specific salt effect.

Table 1. ACTIVITIES IN THE PRESENCE OF CARBON DIOXIDE RELATIVE TO THOSE IN AIR

Carbon dioxide concentration (per cent of 1 atmosphere)	Succinic cytochrome *c* reductase	Reduced diphosphopyridine nucleotide cytochrome *c* reductase	Cytochrome *c* oxidase
0·05 (air)	100	100	100
1·7	—	101	109
4·3	102	110	118
8·7	75	102	135
13·0	—	—	193
17·3	38	108	265
26·0	22	88	248
43·3	14	75	124
60·7	3	44	56
78·0	—	33	25

Low concentrations of carbon dioxide had little effect on reduced diphosphopyridine nucleotide cytochrome *c* reductase, but there was inhibition at higher concentrations. This inhibition was found to be non-competitive with respect to reduced diphosphopyridine nucleotide.

In contrast, the reduction of cytochrome *c* by the succinic system was strongly inhibited by concentrations of carbon dioxide as low as 17 per cent. This inhibition was found to be competitive with respect to succinate, which with spectroscopic and other evidence indicates that the inhibition is of succinic dehydrogenase.

The inhibitions of all three systems were reversible.

The strong inhibition of succinic dehydrogenase can account for the accumulation of succinate in preparations of *Ricinus* mitochondria fed with Krebs-cycle acids in the presence of about 20 per cent carbon dioxide[1]. It can also account for the accumulation of succinic acid in plant organs which are stored in atmospheres containing about 20 per cent carbon dioxide[5,6].

In addition to the increased inhibition of succinic dehydrogenase, the inhibitions of reduced diphosphopyridine nucleotide cytochrome *c* reductase and cytochrome oxidase by concentrations of carbon dioxide above about 40 per cent could be factors contributing to the rapid induction of carbon dioxide zymasis[7] in intact plant organs stored in atmospheres with plenty of oxygen but also containing carbon dioxide in concentrations approaching 50 per cent[7-9].

Mycobacillin, a New Antifungal Antibiotic produced by *B. subtilis*

DURING the studies on the distribution of antifungal organisms in Indian fruits, vegetables and soils, a strain of *Bacillus subtilis* (characterized according to Bergey[1]), highly active against widely different groups of fungi, namely, skin pathogens, plant pathogens, rice-spoilage organisms, etc., was isolated[2].

The optimum cultural conditions for the formation of the antibiotic were studied[3] and the highest yield was obtained in a medium consisting of potato extract, casein hydrolysate, beef extract and glucose. The antibiotic was extracted from the fermentation broth and isolated in a pure state following the method of Babad *et al.*[4]. Ultimately a light-brown mass was obtained which crystallized on cooling and evaporation from 70 per cent alcoholic solution as needle-shaped crystals.

The active substance was chromatographed by a simple one-dimensional strip technique using different developing solvents, and, in all cases, only a single active spot was detected by bio-autographic technique. Several common methods of homogeneity studies also indicated the absence of any inactive impurity in the antibiotic.

The substance was soluble in lower alcohols, acetone, acetic acid, caustic soda, conc. hydrochloric acid, pyridine and in water above *p*H 7·0, but insoluble in water between *p*H 2–7 and also in ether, chloroform, etc. It gave negative Molisch and ninhydrin tests, but positive tests for Millon's reagent, biuret reaction, Folin's phenol reagent and xanthoproteic acid reaction. The substance was more heat-stable in acidic than in alkaline *p*H. The antibiotic contained no sulphur or halogens, and its nitrogen content was 11·9 per cent. Its molecular weight as determined by diffusion method was found to be of about 1,800. It has no activity against *E. coli, Staphylococcus aureus, Streptococcus fœcalis*, etc.; but it possesses a wide antifungal spectrum and it inhibits the growth of *A. niger* at 0·02 mgm./ml. in solid agar medium. Paper partition chromatography of an acid hydrolysate of the antibiotic with two-dimensional method using phenol–water as the first solvent and *n*-butanol–acetic acid–water (4 : 1 : 1) as the second solvent indicated the presence of seven amino-acids, namely, aspartic acid, glutamic acid, serine, alanine, tyrosine, leucine and proline—aspartic acid being present predominantly. The antibiotic is a ninhydrin-negative cyclic polypeptide and is somewhat different from the other known antifungal antibiotics[5] like bacillomycin, bacillomycin *B*, *C*, etc., as regards the nature and number of amino-acids present. This new antifungal antibiotic has, therefore, been designated as 'mycobacillin'.

A more detailed report will be published elsewhere.

Our grateful thanks are due to Prof. B. C. Guha, for his kind interest and encouragement in the course of the work.

Maceration of Plant-tissues with Ethylene-diamine-tetra-acetic Acid

For many years plant anatomists have used macerating techniques[1-3] which subject plant-tissues to either destructive oxidizing agents (usually chromic acid), concentrated acid or alkali, or high temperature. These procedures can cause change in volume of the cells. Macerating media containing chromic acid have been found to destroy cell-walls[3] and the other media referred to above would also be very damaging to plant-cells.

The chelating agent, sodium ethylene-diamine-tetra-acetate, has been found to macerate effectively under conditions (*p*H 7–10, 37–45° C.) which are much milder than those mentioned above. This reagent should be particularly useful for maceration of tissue composed of easily damaged cells and for maceration without change in cell-volume. The macerating action of sodium ethylene-diamine-tetra-acetate is attributed to the ability of the reagent to dissolve the insoluble salts of pectic and low-methoxyl pectinic acids which appear to form a large part of the middle lamella.

The macerating power of sodium ethylene-diamine-tetra-acetate was markedly affected by changes in *p*H. The optimum *p*H for maceration of matured apple-tissue at 45° C. was 10·3. At *p*H 7 and *p*H 11·3 the macerating activity was about 50 per cent of that at *p*H 10·3. Increase in temperature greatly accelerated the rate of maceration. Although the macerating action of the reagent (0·07 *M*; *p*H 10) was appreciably weaker than that of 5 per cent chromic acid, when compared at 37° C. sodium ethylene-diamine-tetra-acetate was 250–300 times more effective than 0·07 *M* ammonium oxalate—an established macerating agent showing appreciable activity only at 100° C. If the osmotic pressure of the 0·07 *M* solution of sodium ethylene-diamine-tetra-acetate was adjusted by addition of sucrose to equal the diffusion-pressure deficit of the cells, maceration of cortical apple tissue could be achieved at 37° C. and 45° C. without detectable change in cell-volume.

For maceration of apple tissue with this reagent the two conditions found most satisfactory are described below. Mid-cortical tissue (1 gm.; cork-borings of 4–5 mm. diameter and length 4–10 mm.) was added to 50 ml. of 0·07 *M* reagent (*p*H 10·7–11·0; adjusted to the correct sucrose-concentration, 0·25–0·40 *M* depending on fruit-maturity). After being shaken continuously for 6 hr. at 45° C., the mixture was left for 16 hr. at 45° C., reshaken by hand and blended at low speed (4,000 r.p.m., M.S.E. micro-homogenizer) for up to 3 min. The blending time required varied with maturity of the fruit. Ripe fruit required no blending. The blendor-blades were covered with water-proof adhesive plaster, and the blendor-cup had baffles inserted into the bulb. The *p*H of macerates was about 10·3. Damage due to sampling of the tissue with the cork-borer accounted for all the damaged cells in the macerates. In macerates of ripe fruit, 80 per cent of the total cells were present as single cells. This procedure was satisfactory for maceration without change in cell-volume.

Maceration with sodium ethylene-diamine-tetra-acetate at 75° C. for 6 hr. with occasional shaking, followed by blending for 1–4 min. has been used for determining the number of cells in apple tissue. In these macerates 88–95 per cent of the total cells were present as single cells.

Carrot-root and potato-tuber tissue (length × diameter of borings = 3 mm. × 5 mm.) can be macerated by the above procedures (the reagent at *p*H 10). The numbers of single cells (expressed as a percentage of total cell-number) in macerates of these tissues obtained by the first method (three-minute blending) are listed below.

Carrot (central cylinder)	66
Carrot (cortex)	27
Potato (tuber)	92

Aggregates composed of more than four cells were seldom found in these or in apple macerates.

Culture of *Nitrosomonas europaea* in Media Free of Insoluble Constituents

SINCE Winogradsky's discovery of *Nitrosomonas* in the latter part of the nineteenth century, members of this genus have been grown in a variety of culture media containing insoluble constituents, the most common of these being calcium carbonate. This component serves as a means of pH control necessary because of the accumulation of large amounts of nitrous acid and also can provide the inorganic carbon source necessary for the autotrophic metabolism of these bacteria. Eventually, it was tacitly assumed that these micro-organisms require adsorption to particulate medium ingredients in order for active proliferation to occur[1,2]. This phenomenon takes on practical significance for soil nitrification in view of the demonstration that substrate ammonium apparently must first be adsorbed before oxidation can commence[3].

In our studies of the biochemical properties of the nitrifying bacteria, it became readily evident that it would be a difficult procedure to separate the cellular material once it became embedded in the excess of insoluble carbonates and phosphates. In order to obtain quantities of cells free of chemical contamination and to determine if there was some obligate adsorption requirement, studies of the growth of these bacteria were initiated using a medium all of the constituents of which were soluble. *Nitrosomonas europaea* was grown in a 30-litre fermentor similar to that described by Johnson[4]. Air sterilized by filtration through sterile cotton or glass wool was dispersed through a 'Selas 01' candle filter. The medium contained 3·0 gm. ammonium sulphate as the energy source, 500 mgm. potassium hydrogen phosphate, 50 mgm. hydrated magnesium sulphate, 4 mgm. hydrated calcium chloride, 100 μgm. chelated iron (Chel–138–HFe, Geigy Chemical Company, New York), and 50 μgm. cresol red in a litre of redistilled water. Additional ammonium–nitrogen was added aseptically in increments as needed. After autoclaving, the medium was brought to pH 8·0 with a sterile potassium carbonate solution, and the culture was maintained at that reaction during the growth-cycle by continuous addition of a sterile 50 per cent potassium carbonate solution, the indicator simplifying this operation.

In the growth-cycle, a lag phase of 10 hr. was observed when a 5 per cent inoculum was used. Following the initial lag, the culture grew at a logarithmic rate for 60 hr. with a generation time of 11 hr. The final nitrite-level at 96 hr. was 1,160 p.p.m. and the corresponding viable count was $1\cdot9 \times 10^8$ cells per ml. The problem of pH control is indicated by the fact that the acid produced in the last 24-hr. period required 6·3 gm. potassium carbonate per litre of medium for neutralization. The relatively short generation time observed and the accumulation of nitrite in concentrations greater than that usually found in media with insoluble carbonates demonstrate that the bacterium can develop at an optimal rate in clear media. Thus, it is evident that these organisms can grow without being adsorbed on to insoluble materials.

The bacterial cells can be separated from the medium by passage through a Sharples centrifuge with the resultant residue consisting of cells devoid of chemical impurities. The cell paste obtained represents a dry-weight yield of about 72 mgm. per litre of culture medium. The colour of this paste is deep red, probably resulting from the presence of a strong cytochrome absorption band. A more complete account of this work will be reported elsewhere.

Effect of Plasmolysis on the Rate of Respiration of a Green Alga

IN some recent experiments to be reported more fully elsewhere, the effect of plasmolysis and of temperature on the rate of respiration of the green alga *Scenedesmus quadricauda* has been investigated. The results may be summarized as follows: (1) At 25° C. there is a highly significant (probability 0·1 per cent or less) decrease in the rate of respiration on plasmolysis, with subsequent recovery on deplasmolysis. (2) At 7° C. there is no effect of plasmolysis on the rate of respiration. (3) Between 5° and 15° C. the activation energy for respiration is of the order of 21,000 cal./mole. (4) Between 15° and 35° C. the activation energy for respiration is of the order of 5,600 cal./mole. These results are independent of the presence or absence of glucose, though above 15° C. the rate of respiration is increased on the addition of glucose, whereas the rate is unaffected below this temperature.

The values of the activation energies suggest that below 15° C. a chemical reaction is limiting the rate of respiration; but above this temperature the rate is limited by the diffusion of a respiratory intermediate. In this case the effect of plasmolysis must be on the diffusion path.

Plasmolysis involves a dehydration of cellular material, and loss of water may occur either from the vacuole or from the protoplasm, or from both. Even if the total loss of water is from the vacuole, the excreted water must pass through the protoplasm, the water content of which may vary until equilibrium is regained. This will be especially true if the permeabilities of the plasma membrane and the vacuolar membrane to water are different. Further, if the plasma membrane and the vacuolar membrane both act as semi-permeable membranes towards the water in the protoplasm and the vacuole, and if there is no movement of solute across the membranes, one would expect water to be lost from both the protoplasm and the vacuole. In cells without or with only very small vacuoles (such as *Scenedesmus quadricauda*) there is likely to be a greater loss of water from the protoplasm in hypertonic solutions than in fully vacuolated cells.

Dehydration of the protoplasm will result in an increase in its viscosity, and this has been demonstrated by Fritsch and Haines[1] for terrestrial algae drying in a desiccator. Under the same conditions, Fraymouth[2] has demonstrated a decrease in the rate of respiration. After centrifuging *Scenedesmus quadricauda* cells for 45 min. at 4,000 r.p.m., a number of larger particles were found to be displaced in normal cells but not in plasmolysed cells, indicating that some increase in viscosity had taken place in the plasmolysed cells.

The equations of Sutherland[3] and of Einstein[4] show that when the radius of the diffusing molecule is large in comparison with the radius of the solvent molecule, the rate of diffusion is proportional to the viscosity of the medium. Stiles[5] held that experimental data disproved these equations, but the data he quoted refer to the diffusion of ions in aqueous solution, and this state of affairs lies outside the Sutherland–Einstein equations. Hitchcock[6] has shown that for diffusion in aqueous solution a molecule will obey the theoretical equations provided that it is no smaller than a hexose molecule.

It is therefore suggested that the decrease in the rate of respiration observed on plasmolysis under conditions where diffusion is limiting the rate of respiration, is caused by a reduction in the rate of diffusion brought about by an increase in the viscosity of the protoplasm. There appear to be two main points in the respiratory mechanism where diffusion in the protoplasm could limit the rate of respiration. The first is diffusion of glucose-1-phosphate, formed by hydrolysis of starch, from the starch grains to the glycolytic system; and the second is the diffusion of the product of glycolysis to the mitochondria. With regard to this suggestion it is interesting to recall that an increase in the viscosity of homogenates has been found to decrease their rates of respiration[7].

Escape Responses of Herbivorous Gastropods when stimulated by Carnivorous Gastropods

Bullock[1] reported that many Californian Gastropoda respond to being touched by tube feet of starfish by crawling rapidly away from the starfish. He also showed that the response differs in details between genera, and between species of a genus; and that some species do not respond at all, or only occasionally. In some species of *Acmaea*, and in *Haliotis cracherodii* Leach 'mushrooming' (raising of the shell well clear of the substratum on the fleshy stalk of the visceral hump) accompanied by lateral swinging of the shell occurred before the animals crawled away; in others, notably the trochid *Tegula*, the animals merely glided rapidly away from the source of stimulation.

Comparable responses may be produced by stimulating herbivorous gastropods with carnivorous ones. This was first observed in Nature on a dry rock surface which had recently been left by the receding tide. A thaisid whelk, *Lepsia haustrum* (Martyn) crawled towards a trochid *Melagraphia aethiops* (Gmelin), and as soon as contact was made between the soft parts of the two the shell of the trochid was lifted well clear of the substratum and swung violently several times through an arc of 180°. The trochid then set off across the rock at two to three times the normal crawling speed. The thaisid did not follow. This has been observed several times. Occasionally, swinging of the shell to left and right is sufficiently violent not only to break contact, but also to dislodge the carnivore, which is several times larger than the trochid.

Similar results were obtained using the starfishes *Coscinasterias calamaria* (Gray) and *Astrostole scabra* (Hutton) as stimulators. The common New Zealand littoral starfish *Asterina regularis* Verrill does not elicit any response. Since making the first observations under natural conditions, many encounters have been 'staged' in tidal pools and in laboratory aquaria. It has been found that freshly collected animals respond in a more marked fashion than those kept in aerated sea water for a few days. As in Bullock's work the vigour of the response varied somewhat between species. The more vigorous reaction involving mushrooming does not always occur; the most common reaction being an abrupt turning away from the point of stimulation, and rapid crawling away from the carnivore. If an animal is stimulated on the right side it turns left and moves away in that direction, and *vice versa*. When contact is frontal the herbivore backs away a short distance before turning to one side and crawling rapidly away. If stimulated repeatedly the herbivores used in the experiments crawled out of the pools or up the sides of the aquarium.

The reactions described here differ from those usually evoked by mechanical stimulation with a needle or human finger. These and other objects cause the animal to lower the shell and cease crawling. Similarly, response to being touched by other herbivores is weak, often causing retraction of a tentacle and a little or no retraction into the shell, but never flight. Carnivores likewise show little or no reaction to being touched by other carnivores.

Herbivorous gastropods found to be sensitive to touch stimuli from carnivorous gastropods are *Melagraphia aethiops*, *Zediloma digna* Finlay, *Z. arida* Finlay, *Z. atrovirens* (Phil.), *Trochus viridis* (Gm.), *Anisodiloma lugubris* (Gm.), *Haliotis iris* Martyn, *Cellana radians* (Gm.), and *C. ornata* (Dillwyn). The fissurellid *Scutus breviculus* (Blainville) and the turbinid *Lunella smaragda* (Martyn) show no response. This may perhaps be explained by the copious covering of mucus on the former, and the heavy calcareous operculum of the latter. The carnivorous gastropoda used as stimulators were *Lepsia haustrum*, *Lepsiella scobina* (Q. & G.), *Buccinulum strebeli* (Suter) and *Cominella maculosa* (Martyn). There appears to be no correlation between sensitivity to different carnivores and position occupied on the shore by carnivores and herbivores. *Lunella smaragda* shows no reaction to *Cominella maculosa*, which lives in the same zone (about mean low water springs), while *Zediloma digna*, which is found at the level of mean high water springs, reacts violently to being touched by *C. maculosa*, which it must rarely, if ever, meet in Nature.

A single specimen of *Lepsia haustrum* was ground up in a pestle and mortar with ground glass and a few ml. of sea water. This was allowed to settle, the supernatant liquor drawn into a pipette, and a few drops placed on the side of the foot of *Melagraphia aethiops*. This evoked a weak reaction. A similar extract of *Mytilus planulatus* Lam. produced no visible results. This tends to support Bullock's view that the stimulus which evokes these reactions is chemical in nature.

A Spurious Significance in Genecological Trials

ATTENTION has been directed[1] to the fact that reduplication of individual genotypes in population sampling gives rise to spuriously low values of the standard error, and hence misleadingly high significance of difference between populations. This naturally leads one to wonder whether reduplicated genotypes are at all frequent in population samples. Further work on perennial plants of hill grazings has now suggested that the risk of reduplication is very high in some cases.

Detailed morphological examination of plants isolated from the wild has revealed numerous cases of strikingly similar isolates, and these are always from points relatively close together; isolates from greater distances apart never being so similar. In a few cases the separate isolates within a similar group have been cloned and laid out in a replicated trial, and it is found that they cannot be distinguished by any scored character: a block of twelve isolates each replicated ten times appears like a block of 120 ramets of a single plant. (In cases where an apparently similar yet distinct isolate has been included in a trial, that one can be picked out in every replication.) It is very tempting to regard such a group of similar isolates as being of a single genotype. Clearly such an assertion can never be proved, but the results of certain lines of investigation have no other simple interpretation. For example, it is found that virtually self-sterile isolates set no more seed on crossing with an apparently identical isolate than they do on selfing; yet they set seed freely when crossed with recognizably distinct isolates. If the interpretation is correct, then the experimental results give a clear impression of the extent and abundance of individual genotypes in natural communities, and an indication of the chances of genotype reduplication in sampling.

One genotype of *Festuca rubra* appears to have a spread of 250 yards, and over this range it is abundant, forming 70 per cent of the isolates from central parts falling to 3 per cent at one point on the margin: over some nine acres one-third of the tillers isolated belong to this one clone. At one part of the range a separate collection was made of nearly 1,500 tillers, isolated at 9-in. intervals from within a 10-yard square quadrat. Approximately 47 per cent of the tillers were referable to this one clone. Other 'large' cones accounted for 12, 6 and 4 per cent of the tillers respectively. A further 39 clones were isolated less than 25 times (1·7 per cent) each, while 105 isolates remained ungrouped and possibly represent genotypes isolated only once each. This clearly suggests a log distribution[2]. The second and the third largest clones, both of which were markedly localized within the quadrat, have not been found elsewhere. The fourth largest clone, however, which was scattered over the quadrat, has a total spread of at least 100 yards. If this picture of genotype distribution is typical of the species in general, then population sampling in *Festuca rubra* at a higher rate than one plant per acre is likely to lead to spurious significance.

In *Holcus mollis* (the pentaploid form) the picture appears to be slightly different in that only 'large' genotypes occur. In an area of 300 yards across only three genotypes seem to be present, each of them widespread and isolated many times. This suggests that new genotypes are not being established.

It appears the clones of *Festuca ovina* do not often exceed four yards in diameter. This comparatively meagre spread is in fact a surprising performance when one considers its growth habit: the age of such a clone is probably to be measured in hundreds of years. It seems likely that in this species spurious significance can be avoided by adopting a suitably restrained sampling technique. In fact, genotype reduplication might not occur to a serious extent in normal sampling procedure, and it may be instructive to reflect that in this species no difference has been found between populations from neighbouring but ecologically distinct sites[1].

The assumed age of some genotypes in all three species is not without its genecological interest. The most recent products of breeding and selection are apparently no more suited to the prevailing environment than their forebears of scores of generations back. Furthermore, the territories concerned are non-uniform and in spreading outwards single genotypes of both *F. rubra* and *H. mollis* have been able to enter, and compete successfully in, any habitat which does not actually exclude that species, suggesting that there is little genecological specialization present.

Finally, it should be pointed out that, since it is unlikely that any two seedlings are identical in genotype, one way of avoiding genotype reduplication is to raise population samples from seed. Unfortunately, however, this need not avoid spurious significance since the variance between the seed progeny of a single plant is almost certainly lower than that between plants of different parentage.

A complete account of this work is being prepared for publication elsewhere.

FORTHCOMING EVENTS

Monday, January 13

Royal Statistical Society (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Monsieur M. Brichler: "Classification of the Population by Social and Economic Characteristics".

British Society for the History of Science, Philosophy of Science Group (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. I. J. Good: "Could a Machine Make Probability Judgments?"

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "The Use of Electricity in the Garden by Amateurs", opened by Mr. M. M. Harvey.

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. Duncan Carse: "South Georgia Survey".

Tuesday, January 14

Institution of the Rubber Industry, London Section (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 5.30 p.m.—Mr. F. N. B. Bennett: "Modern Testing Methods and Equipment"; 7 p.m.—Mr. W. S. Penn: "New Synthetic in Cables".

Institution of Mechanical Engineers, Automobile Division (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Dr. T. P. Hoar: "The Prevention of Corrosion in Car Bodies".

Wednesday, January 15

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Mr. Stanley Gooding: "Modern Research into Bees and Bee-Keeping".

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Scientific Papers.

Institute of Physics, London and Home Counties Branch (at 47 Belgrave Square, London, S.W.1), at 6 p.m.—Dr. B. F. J. Schonland. F.R.S.: "Physical Research in the Research Group of the Atomic Energy Authority".

Institute of Metals (at 17 Belgrave Square, London, W.C.1), at 6.30 p.m.—Dr. David Turnbull: "The Mechanism of Clustering and Precipitation in Metals".

Royal Institute of Chemistry, London Section (joint meeting with the London Section of the Society of Chemical Industry, at the College of Preceptors, 2 and 3 Bloomsbury Square, London, W.C.1), at 6.30 p.m.—Prof. W. E. Garner, F.R.S.: "Recent Advances in Catalysis".

Society of Chemical Industry, Corrosion Group (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. T. P. Hoar and Mr. J. G. Hines: "Stress Corrosion Cracking".

Thursday, January 16

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—General Meeting.

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. A. S. Besicovitch: "Sharpening some Lebesgue Theorems".

Chemical Society (in the Large Chemistry Lecture Theatre, Imperial College of Science and Technology, South Kensington, London, S.W.7), at 7.30 p.m.—Prof. D. H. R. Barton, F.R.S.: "Some Aspects of Sesquiterpenoid Chemistry" (Inaugural Simonsen Lecture).

Royal Society of Tropical Medicine and Hygiene (at 26 Portland Place, London, W.1), at 7.30 p.m.—Symposium on "Onchocerciasis".

Friday, January 17

Royal Society of Medicine, Epidemiology and Preventive Medicine Sections (at 1 Wimpole Street, London, W.1), at 5 p.m.—Symposium on "Weather and Disease".

Institute of Navigation (at 1 Kensington Gore, London, S.W.7), at 5.15 p.m.—Mr. J. R. Saxton: "The Influence of Atmospheric Conditions on Radar Performance".

Saturday, January 18

British Psychological Society (in the Psychology Department, Birkbeck College, Malet Street, London, W.C.1), at 2.30 p.m.—Dr. R. Melzack (University of Oregon Medical School): "Some Recent Experiments on the Problem of Pain".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Biochemist, Basic grade (with a science degree)—The Group Secretary, Doncaster Hospital Management Committee, Doncaster Royal Infirmary, Doncaster (January 18).

Lecturer in Electrical Engineering—The Registrar, University College, Singleton Park, Swansea (January 18).

Head (well qualified graduate of a British university) of the Electrical Engineering Department—The Clerk to the Governing Body, Battersea College of Technology, London, S.W.11 (January 20).

Chair of Botany tenable at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W.C.1 (January 29).

Lecturer in Inorganic Chemistry at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, January 31).

Lecturer in Mathematics at the University College of Ghana—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (January 31).

Lecturer in Physics at the University of New England, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, January 31).

Reader in Organic Chemistry at King's College, Strand, London, W.C.2—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 1).

Lecturer in Chemistry at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 8).

Lecturer (with a knowledge of mathematical statistics) in Pure Mathematics—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (February 8).

Lecturer (preferably with experience of virus work) in Bacteriology; and a Georgina McRobert Fellow, to investigate the cause, prevention and treatment of cancer—The Secretary, The University, Aberdeen (February 14).

Imperial Chemical Industries Research Fellows in Physics, Chemistry, Engineering, Metallurgy and Pharmacology or any related subjects—The Registrar, The University, Liverpool (February 15).

Senior Lecturer in Numerical Analysis at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 15).

Imperial Chemical Industries Research Fellows (4) in Chemistry, Physics, Physical Chemistry, Biochemistry, Chemotherapy, Pharmacology, Pharmacy, Colloid Science, Metallurgy, Engineering, Geology or Agricultural Science—The Registrar of the University of Wales, University Registry, Cathays Park, Cardiff (March 8).

Turner and Newall Research Fellow in Engineering, Inorganic Chemistry or Physics or other allied science—The Registrar, The University, Leeds 2 (April 12).

Assistant Lecturer (Grade B) in Chemistry—The Principal, Royal Technical College, Salford 5.

Assistant (man or woman, with a good reading knowledge of Russian) for abstracting scientific papers in economic entomology—The Director, Commonwealth Institute of Entomology, 56 Queen's Gate, London, S.W.7.

Bacteriologist (with the Ph.D. degree) to undertake research on the physiology and biochemical activities of bacteria and to supervise the maintenance of a culture collection—Dr. G. A. Ledingham, Director, Prairie Regional Laboratory, National Research Council, Saskatoon, Saskatchewan, Canada.

Chair of Psychology—The Registrar, The University, Bristol.

Entomologist (with a good honours degree in an agricultural science and at least two years postgraduate experience in entomology) in the Agricultural Department, Sierra Leone, to organize control measures for insect pests of coffee, cocoa and other crops—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/15/011.

Histological Technician (preferably with the diploma of the I.M.L.T. in histology) in the Department of Morbid Anatomy—Dr. M. Bodian, Department of Morbid Anatomy, The Hospital for Sick Children, Great Ormond Street, London, W.C.1.

Research Worker (with a degree in psychology)—The Director, Burden Institute, Stoke Lane, Stapleton, Bristol.

Scientific Officer (Chemist) (with a first- or upper division second-class honours degree in chemistry of equivalent qualification, and preferably at least two years postgraduate experience in inorganic analysis and a specialized knowledge of silicate and/or spectrographic analysis) in the Department of Geological Survey, Federation of Nigeria, for duties which include the analysis of rocks, ores and minerals in the Geological Survey Laboratories—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.105/14/09/T.

Technician (Associate of the Institute of Medical Laboratory Technology) in the Department of Surgery, University of Oxford—Nuffield Professor of Surgery, Radcliffe Infirmary, Oxford.

Technician (with the A.I.M.L.T. or equivalent qualification), for duties mainly consisting of assisting with research—The Secretary, Guy's Hospital Medical School, London Bridge, London, S.E.1.

PLASTIC PHOSPHOR NE 102

Our new plastic scintillator possesses extremely high light output (60/65% anthracene) and combines superior performance with greatest economy. Available from stock in any shape up to 400 lb. mass or in thin sheets for alpha and beta ray counting or in rods up to 24 in. diameter. Rough ingot form at considerably reduced cost. NE 102 is the lowest cost plastic phosphor ever offered. For fuller details write for Bulletin 11.

OTHER PRODUCTS & SERVICES
(described in Bulletins 9, 9A, 10, 12 and 13)

- Scintillating Gels, for efficient internal counting of suspended materials.
- Boron, Cadmium, Gadolinium and Lead Loaded Liquid Scintillators for neutron detection, or for enhanced gamma response.
- Liquid Phosphors—Encapsulated, or in bulk form at new low prices.
- Super-pure Scintillation chemicals.
- Boron polyester plastic Scintillator NE400 for neutron detection. Extreme sensitivity even in high gamma ray fields. Available with enriched Boron.
- Nuclear equipment built to your specifications.

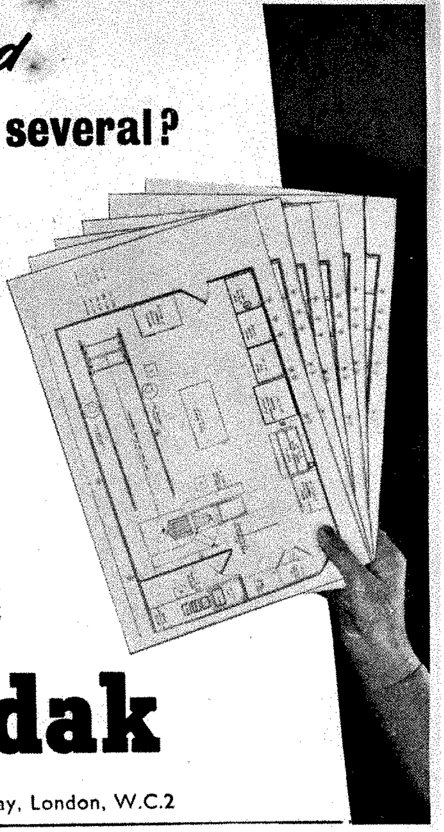
Do you need

one copy—or several?



Every organisation has its own particular document-copying requirements, so you alone can decide which copying method would be most suitable for your purposes.

For example, is time a very important factor? Would you require one copy of a document, or several? Would originals be single-sided or double-sided? Who would use the equipment? Would copies have to be despatched immediately? These and other factors must influence your choice.

So before you start buying, get in touch with Kodak, who have an immense amount of document-copying experience behind them. They will provide you with a great deal of information that should help you to select the most suitable method for your particular needs.

PROBLEMS OF GOVERNMENT IN THE MODERN WORLD

For something like two decades at least, it has been widely recognized in Britain that Ministers and the higher Civil servants have been seriously overworked. Indeed, the Haldane Report on the Machinery of Government in 1918 urged the importance of more provision for investigation and thought as a preliminary to action, and this is the proper approach to a problem that in recent months has been described as one of reducing the burden on Ministers.

It was suggested to the Prime Minister in April last that he should appoint a Select Committee to review and inquire into the working of the present system of government with the view of reducing the burden on Ministers and also securing the more efficient working of Parliament. After studying the suggestion, Mr. Macmillan invited a small group of Privy Councillors with long experience of the House of Commons to make a preliminary informal study of these problems under the chairmanship of Lord Attlee. Their report was presented early last autumn, and Mr. Macmillan stated on November 5 in the debate on the address from the Throne that he was satisfied that no further inquiry is required and that the problem is one of adapting existing practices to the best advantage. He said further that it is not easy for Ministers in charge of departments to retain full responsibility, as they must, and at the same time take complete advantage of the help that Parliamentary Secretaries and Ministers of State can give. If such Ministers are really to be regarded as deputy Ministers they must be recognized as having such authority, and he thought that this might be the biggest single contribution to the reduction of the burden on senior Ministers. Mr. Macmillan suggested that members of the House might accept such Ministers as the spokesmen of their Departments. Independently of this, the Prime Minister was specifically challenged on October 29 about the responsibilities of the Lord President of the Council. The Opposition was plainly dissatisfied at the combination of the major departmental responsibilities for the nation's scientific effort with party political duties; but the matter was raised in too partisan a manner to bring out the real reasons for concern.

Those reasons appear much more clearly in a survey by a study group of the Royal Institute of Public Administration which has been published under the title "The Organization of British Central Government, 1914–1956"* since the Committee of Privy Councillors began its inquiry. Particularly in its chapters on the central administration, the central co-ordination of Government and the handling of administrative change, it supplies the background for fruitful discussion of the current problems of government, while the chapter on scientific research provides a coherent picture of the organization in Britain for research. This is of special importance at the present time in view of the survey on which the Advisory Council for Scientific Policy is already engaged, and also because of its bearing on effective scientific co-operation with the United States, to which the Prime Minister and President Eisenhower have committed us.

The Prime Minister, however, made two remarks in referring to the accident at Windscale which are profoundly significant in this connexion. In replying to questions arising out of his statement on November 8, he remarked that on the purely technical atomic aspects of the accident, he had chosen Sir Alexander Fleck to be chairman of the three committees because he had sufficient scientific knowledge of a general character. Secondly, when asked on November 12 whether, in view of the fact that responsibility for nuclear energy matters involves much detailed study of highly technical problems, he would consider transferring that responsibility from himself to a senior Minister in the House of Commons, he replied that he thought the existing arrangement is the most suitable at the present time. Pressed again that in principle it was wrong that the Prime Minister should be burdened with detailed affairs that are bound to arise from time to time in an organization such as the Atomic Energy Authority, Mr. Macmillan admitted that there are disadvantages. Nevertheless, he thought that, for the present, when the various uses of nuclear power are so much in the field that the Prime Minister of the day must in any event have them under his control, there are advantages, and that on the whole the system works well. In the detailed work he was much helped by the Paymaster-General.

Now there are at least three implications in these remarks that bear profoundly both on the whole conduct of government and on its organization in relation to the nation's scientific and technological effort. Implicit in the reason given for his choice of Sir Alexander Fleck and in his reason for retaining as Prime Minister special responsibility for nuclear energy is the fundamental importance of some personal understanding of science and technology on the part of Ministers and of their chief permanent advisers. Consciously or unconsciously, Mr. Macmillan underlined the vital point which Sir Henry Tizard made in his Haldane Memorial Lecture. Without such understanding of science on the part of Ministers and members of the administrative class of the Civil Service, there cannot to-day be secured that effective relation between knowledge and power, and between expert and responsible Minister, upon which the smooth functioning of any system of government depends.

---

* The Organization of British Central Government 1914–1956: a Survey by a Study Group of the Royal Institute of Public Administration. Edited by D. N. Chester. Written by F. M. G. Willson. Pp. 458. (London: George Allen and Unwin, Ltd., 1957.) 32s. net.

The first task is thus attention to the educational system—and at all levels—not simply to secure the supply of sufficient scientists and technologists, but also of Ministers, administrators and citizens who are able to appreciate the significance of what the scientist or technologist is doing, and of scientists and technologists who are capable of taking broad views and of explaining the significance of their investigations in terms which those working in other fields can understand. This is an urgent task and of over-riding importance. While its results may well be long-term, the course of Anglo-American co-operation and Britain's security, as well as her economic future, largely depend on the vigour and vision with which it is undertaken.

Next, there is implied the necessity of considering the scientific and technical aspects of public affairs at the highest—at the policy-making—level. This is not to say that the scientist or technologist as such should be present in the Cabinet; but it does involve the presence at that level of those who are competent to evaluate at first hand the advice on such matters that their experts have given them. It is difficult to believe that the Advisory Council on Scientific Policy or the Defence Research Policy Committee has failed for the past ten years to present its advice cogently and intelligibly, though the published reports of the former body suggest that on occasion it might have been expressed more firmly or forcibly. It is much more probable that its significance and especially the urgency of action in such matters have rarely been appreciated at Cabinet-level, and matters have usually been allowed to drift, with waste of precious resources, until some less-effective measure has had to be adopted, often with further waste and frustration.

This view is supported by the picture which is presented in the chapter on scientific research in "The Organization of British Central Government, 1914–1956". That chapter traces the development of government institutions which have been specially established to conduct—and to encourage private institutions to conduct—scientific research primarily for civil purposes; but it also discusses succinctly some of the problems which have been raised by the assumption of this new Government responsibility. Sufficient is said about the University Grants Committee to show that the arrangements for co-ordination of the resources for fundamental research are quite loose, and that without real understanding and insight at the Treasury and on the part of the Lord President of the Council, not only is overlapping possible, but also and more important, research of outstanding significance can be restricted by economy measures dictated by those with no direct responsibility for the work or appreciation of its bearing on the national welfare or economy. The importance of co-ordination is implicit in the remarks of the Prime Minister, though he did not indicate that he proposed to improve the existing arrangements.

Several types of authority have been established over the years to deal with government policy in scientific research. It seems to be generally admitted that the orthodox type of government department is not suitable where research is concerned. What stands out above all, however, is the dependence of the structure as a whole upon the vision, understanding and influence of such men as Lord Balfour and the late Lord Waverley. Where such interested and strong personalities have held the office of Lord President, the system has manifestly worked; in their absence it is difficult to believe, on this record, that a theoretically perfect organization would have yielded better results.

The conclusion is drawn from this survey that the research authorities should have a high degree of autonomy and be regarded as institutions with entirely non-political functions, the necessary minimum of control being exercised on behalf of Government and Parliament by a Minister with no departmental responsibilities and consequently no departmental prejudices—namely, the Lord President of the Council. For that reason, it would seem a sound decision to transfer to the Minister of Power the responsibilities for nuclear energy which the Lord President held from January 1954; but it is more debatable whether the responsibilities for nuclear research should also be transferred, particularly in the present situation, when the balance of research and development effort is in question. The Lord President seems better placed than any other senior Minister to determine whether the resources allocated to nuclear research and the development of nuclear energy, both under the Atomic Energy Authority and elsewhere, are excessive or not. The responsibility is immense, and the real criticism made of the structure up to April 1957 was that the Lord President was ill-provided for such responsibility either in respect of staff or spokesmen in the House of Commons; nor does it seem satisfactory that there should still be two indirect spokesmen—the Parliamentary Secretary to the Minister of Works and the Paymaster-General. The conception of a Minister of Science has been rejected for valid reasons, but the case for providing the Lord President of the Council with such an organization and staff for research and intelligence generally as the Haldane report recommended seems unanswered.

Until the outbreak of the Second World War the Lord President, despite his special responsibility for the research councils, was only slightly in evidence as a scientific co-ordinator, and the prestige which Lord Salisbury's predecessors in that office enjoyed was largely built up when Sir John Anderson, as he then was, was Lord President, from October 1940 until September 1943, and acted as chairman of two standing committees, one on economic information and one on scientific research. Later, in 1947, the economic responsibilities were relinquished and about the same time the Advisory Council on Scientific Policy and the Defence Research Policy Committee were established. Moreover, from January 1956 until April 1957, besides carrying responsibilities for the major scientific organizations, the Lord President presided over the Cabinet Committee on Atomic Energy, consisting of those Ministers who have a share of responsibility in the activities of the Atomic Energy Authority, and probably others, and he was assisted by an official committee of high Civil servants drawn from the corresponding departments.

Thus far the survey made by the Study Group of the Royal Institute of Public Administration scarcely supports the manner in which scientific policy has been handled by Government in recent years; and it points to the wisdom of a suggestion made by Sir John Anderson in his Romanes Lecture of 1946, that a section of the Cabinet Secretariat should be organized to assist the Lord President as the Minister responsible for the general aspects of scientific investigation, thus providing scientific advice at the highest level without prejudice to the work of departmental scientific staff. But the discussion of the handling of administrative change in general is even more pertinent to the question of lightening the burden on Ministers and facilitating deeper thought on policy and problems of change now under consideration by the Prime Minister. There is indeed no simple formula by application of which all problems of administrative arrangement can be solved. The structure of central government and the distribution of functions among departments is the resultant of numerous factors. Obviously, the number of Ministers will be determined ultimately by the responsibilities which the central government is required to assume, and on the whole it is remarkable, with the great increase in government activity during the past forty years, that the number of Ministers has increased no more than from twenty-one in 1914 to twenty-nine in 1956.

It would not appear from the Prime Minister's comments so far that he intends to enter on any discussion either of the two powerful forces which since 1914 have dominated this struggle about the number of Ministers, or again of the four main ways in which Government powers and activities may be grouped for administrative purposes. It could perhaps be inferred that he himself gives greater weight to the needs of co-ordination and the advantages of government by a small and well-knit body of Ministers and also that he attaches greater weight to the purpose to be served than to the kind of work to be undertaken. That again might be less important if there were evidence that Governments could count on a succession of Lord Balfours and Lord Waverleys competent both to give due weight to the scientific and technical elements in affairs of state and also authoritative enough to ensure that the conditions in which scientific research is most fruitfully pursued are preserved and that adequate resources are available.

Although the essential factors to be considered in handling changes in the administrative structure are set forth in this book with admirable lucidity and in a way that could reduce the possibility of an inefficient allocation of functions, the Study Group of the Royal Institute of Public Administration is careful not to suggest excessive attention to this aspect. On the whole, it seems satisfied with the present arrangements within the Treasury for handling such questions, and considers that the structure has been changed and extended with a fair degree of success to meet the conditions of to-day. Problems indeed remain: more use might be made of men and women of affairs outside the Civil Service, and also of students of public administration, as indeed was envisaged in a Government pledge of 1948. It also advocates the publication from time to time of a report surveying the changes in the machinery of government during the period covered, and giving as much information as possible as to the reasons for the changes and about any studies or inquiries conducted since the previous survey.

Such publicity is a pre-condition for the informed discussion which alone can put at the disposal of the Government the full range of experience and the profoundest thinking available in the nation; and it should be kept in mind by Mr. Macmillan in considering the publication of the report of the Committee of Privy Councillors, and indeed of those of the Machinery of Government Committee. Although the process of adaptation is now more conscious than formerly, and more attention is paid to the broad plan of organization on which Ministers rely for the discharge of their powers, efficiency will be promoted by constant study of the factors influencing the structure of government, subject always to the need for flexibility.

The beginning of wisdom in this context, this study affirms, is the firm rejection of any belief in the possibility of defining a rigid and comprehensive framework of organization into which every function of government can be fitted for all time. Perhaps one of the gravest dangers, as we have seen on occasion in respect of the nationalized industries, is that flexibility or other principles of sound administration may be disregarded through party political prejudice or some other partisan view.

The issues raised by the Prime Minister's statement as to the responsibilities and duties of Ministers go right to the heart of the efficiency of government. Part of the problem lies in relieving the central government of detailed work which is best carried out regionally or locally, and that in turn depends on restoring vitality and efficiency to local government. Here, too, is a problem of communication, and in that respect it would appear that we have far to go to secure really effective contact and understanding between the centre and the perimeter. Nor is this solely a matter of seeing that our rulers and administrators are appropriately educated: at least in part it is a matter of ensuring that full use is made of the possibilities of communication and interpretation now at our disposal.

The vital need at the present time is for an educational system, perhaps on the lines put forward in general terms by Sir Eric Ashby, Dr. J. Bronowski and Dr. R. P. Linstead in recent addresses, which will provide the nation with leaders capable of assessing all aspects of the problems which the modern world presents, and wise and strong enough to resist sectional pressure.

A SYNTHESIS OF GENERAL EMBRYOLOGY

Introduction to General Embryology

By Prof. A. M. Dalcq. Translated by Jean Medawar. Pp. vii+177. (Oxford: Clarendon Press; London: Oxford University Press, 1957.) 25*s*. net.

THIS "Introduction to General Embryology" is the outcome of a series of thirteen broadcast talks given by Prof. Albert Dalcq in 1951 at the request of the "Université radiophonique" of Paris. These lectures were published in French by Prof. Dalcq in 1952, under the title "Initiation à l'Embryologie générale". This small book soon became a classic for students—not only Prof. Dalcq's own, but also for those of his former students who, like the present reviewer, have the task of teaching experimental and chemical embryology in university courses. In fact, Prof. Dalcq's book is much more than an introduction to embryological problems; it is a masterly synthesis of our present knowledge in the field, as well as the expression of the scientific and philosophical ideas of one of the world's leading embryologists. The translation of Prof. Dalcq's book into English is especially welcome, since the author has brought up to date the first nine chapters of the French edition, has rewritten the remainder and added a new chapter devoted mainly to his recent important work on mammals.

Prof. Dalcq starts with a question that is puzzling for too many laymen: Why should one study embryology? After showing the importance of this science for practical (artificial insemination) and medical purposes, he emphasizes the close relationship existing between embryology and allied disciplines (cytology, genetics, study of evolution). He points out—and this is one of his favourite ideas—that the main abilities of the human mind are all inborn: the nature of psychic activity might be discovered from studies made on the embryo. It is perhaps one of Prof. Dalcq's secret hopes that a psychological analysis of the developing embryo will some time become a reality.

Chapter 2 is a clear and brief account of the history of embryology. The reader is immediately placed in the middle of the eternal preformation *versus* epigenesis controversy. The next chapter is devoted to the methods used by present-day embryologists.

In Chapter 4, the main cellular constituents, at the morphological and biochemical levels, as well as the formation of the gametes, are briefly described. The next chapter deals mainly with fertilization and parthenogenesis. The title of Chapter 6 is "A Discussion of Terminology": after describing cleavage and gastrulation, Prof. Dalcq concludes that ontogenesis begins necessarily with immediate or delayed cleavage; morphochoresis corresponds to both gastrulation and neurulation; it is followed by cytodifferentiation and growth.

The next chapters introduce the reader to the realm of experimental embryology. The classical experiments in which one of the blastomeres of the two-cell stage is destroyed, or in which the two blastomeres are separated from each other are clearly described and discussed. The significance of, and the difficulties inherent in the use of, such terms as mosaic and regulative eggs are stressed. Prof. Dalcq also explains what he means by "normogenesis" and "paragenesis"; normogenesis and regulation are at the two extremes, while paragenesis corresponds to the intermediary anomalies of development, including exogastrulation, morphogenetic induction in vertebrate eggs, vegetalization or animalization in those of the sea urchin, etc.

In Chapter 10 the author analyses the many aspects of induction and introduces the very useful concept of "morphogenetic potentials". This is followed (Chapter 11) by a very interesting study of mammalian development, including Prof. Dalcq's important studies on the cytochemistry of these eggs.

The scope becomes still broader in the next two chapters, which are devoted to the relationship between development, heredity, and evolution. Finally, in the last chapter, "Where do we stand?", Prof. Dalcq brings together many facts derived from studies of asexual reproduction, regeneration, and embryonic development. He finishes this attempt at synthesis with a few remarks that summarize his philosophy of life and the living.

One must heartily congratulate the translator, Mrs. Jean Medawar, on her expert job. Prof. Dalcq's style is elegant, elaborate, and precise. That all these qualities are found again in the English text deserves admiration. The presentation of the book is excellent and there are next to no typographical errors. Thanks to the quality of the paper, the reproduction of text figures (many of them original and slightly schematic) is much better than in the original French edition.

J. BRACHET

AGRICULTURE IN EAST AND WEST

Types of Rural Economy

Studies in World Agriculture. By Prof. René Dumont. Pp. xii+556. (London: Methuen and Co., Ltd., 1957.) 45*s*. net.

PROF. DUMONT is already well known for his studies of French agriculture: in this volume he ranges over a much wider field, including England, most of Europe, North and West Africa and northern Viet Nam, always, however, confining himself to places he has actually visited. The book is thus a series of vignettes, but the background is always broadly sketched in to keep a sense of proportion. In a disarmingly modest preface he describes the volume as a "preliminary exercise" by one who undertook these economic studies "too late in life to have acquired a really profound knowledge of them", but the apology is quite unnecessary: the most expert reader will gain a great deal from its pages.

The author's keen power of observation, and his ability to pick out and emphasize the essentials of the various systems described, give the book an exceptional value. He is equally interesting and informative whether he is dealing with the collective farms near Moscow and in Eastern Europe, the corridor system in the Belgian Congo designed to overcome the defects of the native shifting cultivation, or the skilful adaptation of agricultural systems to environment in the Alps.

He makes some shrewd and penetrating comparisons of British and French agriculture, one worked by tenant farmers, the other by peasants: characteristically he began his studies by working as a labourer on a small Shropshire farm. The English farmer, he found, operates on a larger scale, reduces manual labour to a minimum by heavy mechanization (the heaviest in the world, he states), prefers tenancy to ownership because he wants to use all his capital for working and development, devotes himself entirely to management, leaving the manual operations to the staff, and enjoys a social status such that "it would not be considered unusual for him to marry a woman qualified in law or medicine. In France," the author adds rather wistfully, "things are quite different." British agricultural policy he regards as the most enlightened in the world; it encourages high output and rural prosperity, and he specially notes that some of the farm workers had motor-cycles or even cars. But he foresees future troubles: we can produce only about half our food and must import the rest; our industrial supremacy has gone, and the terms of trade are moving steadily against importers of food.

Like others who know them, he praises highly the land reclamations in Holland, the most impressive in the world, though with the reservation that urban developments are throwing land out of cultivation more rapidly than new land is brought in: better urban planning could avoid this. Also he is doubtful about the ethics of British and Dutch nurserymen who between them burn a million tons of coal a year to grow early grapes and other fruits—purely luxury products: if the buyers would only wait a month or so they could obtain better flavoured fruits from the Mediterranean countries. Actually by far the chief products are tomatoes, cucumbers, lettuces, and other salads badly needed in our diet.

Italy deservedly receives considerable attention: no other country is experimenting with so great a variety of agricultural economic systems to deal with the problems of too many people multiplying too rapidly and trying to live on too few resources. The range is widened by the circumstances that the natural conditions are favourable in the north but become less and less so in travelling southwards. Individualist, communist, co-operative, metayage, mandatory labour, and other systems are under trial.

Having completed his wide survey ranging from primitive African to intensive Western European systems Prof. Dumont summarizes his conclusions. The greatest obstacle to agricultural progress lies in the smallness of the units in many countries. He is all in favour of the large, indeed the very large farm, and prefers the Russian collective or the Eastern European group-cooperative to the Western capitalist system, but only on the condition that membership be genuinely voluntary. He sees, however, the danger that it may foster the growth of a swollen and incompetent bureaucracy. Against the large capitalist farm are the facts that it is based on the profit motive, which he heartily dislikes, and that the workers lack the spur of personal interest—he does not discuss bonus payments. Whatever the system, however, capital must come in from outside to provide the necessary equipment: he gives striking examples showing the enormous benefit thus conferred. Prior to 1820, there was, perhaps, a ten-fold difference in efficiency between the various systems of agriculture in the different countries he has studied: the production of one cwt. of grain required about three-quarters to 7½ days of labour. The native African and Asian systems still require this. But in the highly developed countries the difference is enormously widened: it is no longer tenfold but more like forty- or fifty-fold; indeed, in the Corn Belt of the United States 5 hours' labour suffices to produce 24–48 cwt. of hybrid maize. The British reader will note that the period concerned corresponds exactly with that of industrial development, and will draw the conclusion that industrial and agricultural development must proceed *pari passu*, that agriculture advances best where workers can be taken off the land and put into factories to provide it with capital and to make the implements, the fertilizers, pest- and weed-control and other agents necessary for high output; when also a teaching organization has been developed to educate the farmers and farm workers, and a research organization to discover the principles governing the growth of plants and of animals so that new and better methods may constantly be devised and tested. Prof. Dumont prefers to insist on a fundamental re-orientation of national effort: the substitution of the present system of economy based on profit for one based on the fight against world hunger. This would necessitate a planned economy imposed on large-scale units operated on liberalized communist lines which he thought he saw emerging, and for which he pleads in an eloquent peroration. But this was written in 1953: in a postscript added in 1957 he sadly records the shattering of his hopes by the tragic events in Budapest.

The book is extremely interesting, written in the best French tradition of idealism tempered by a shrewd sense of the practical. Mr. Douglas Magnin, the translator, has done his work well, and his text reads as smoothly and persuasively as the original.

E. John Russell

THE CHEMISTRY AND BIOCHEMISTRY OF THE REDUCTONES

Chemie und Biochemie der Reduktone und Reduktonate

Von Prof. Dr. Hans von Euler und Prof. Dr. Bernd Eistert. Pp. xi+344. (Stuttgart: Ferdinand Enke Verlag, 1957.) 47.40 D.M.

The compounds designated reductones contain the grouping R—C(OH)=C(OH)—R'. As would be expected from their structure they display intense chemical reactivity, notably in their reducing power towards reagents such as dichlorophenol-indophenol (Tillmans reagent). The endiol grouping is found in a wide variety of organic substances, including both synthetic materials and substances of natural origin. One of the most important of these is L-ascorbic acid (vitamin C) and interest in the very novel problems encountered during the study of ascorbic acid and its analogues stimulated investigations into the general problems of reductone chemistry.

In the present volume three of the principal workers in the field, namely, H. von Euler, B. Eistert and H. Hasselquist, have collected together information from a wide range of publications and have presented it in a form which makes it readily available to other workers in this field. A brief glance at the lengthy list of names of authors and substances given in the index and at the very numerous references to original papers recorded page by page in footnotes will suffice to show that their task has been truly formidable. An astonishing variety of topics is discussed in the course of twelve chapters and a short appendix. Methods for the recognition and determination of reductones are given in detail in the first chapter, followed by a chapter on the endiol forms of the aliphatic and aromatic acyloins. This leads to a discussion of the complex forms of tautomerism displayed by the reductones. There are detailed accounts of the chemistry of the simplest member (triose reductone) and its derivatives, of reductones containing thiol or amino groups, aromatic and heterocyclic reductones, vinyl-homologues of reductones, and substances of the reductic acid type. Two of the main chapters are devoted to ascorbic acid and its derivatives, and to a consideration of the biochemistry of vitamin C and its analogues.

The book will be of great value to all whose work involves compounds containing the endiol system ($—C(OH)=C(OH)—$) or its dehydro form ($—CO—CO—$). Clear accounts are given of the theoretical background to the synthetic reductones, but in the important case of L-ascorbic acid one looks in vain for a connected statement of the evidence upon which the accepted structure is based. The necessary information is indeed recorded (although in ref. 7 on p. 196 the name of the journal is incorrect), but it is found in various places, and there is little indication of the many fundamental problems presented by the chemistry of ascorbic acid and its analogues.

In the chapter on biochemical aspects—where admittedly the number of possible references is legion —it is a pity that an omnibus reference to a review article (p. 305) should tend to obscure the very important part played by S. S. Zilva in the development of our knowledge of vitamin C. In view of the recent work by Calvin, it is doubtful whether many chemists would agree that glycolaldehyde (p. 298) or formaldehyde (p. 309) can be regarded seriously as precursors of the carbohydrates in photosynthesis. One feature is, however, well brought out in this section—namely, the extraordinary complexity of the problems involved in ascertaining the biological role taken by L-ascorbic acid and the little progress that has been made in this field despite all the efforts of the past few years.

It is clear that the reductone system still holds many important secrets both for the chemist and the biologist to uncover. E. L. HIRST

PHYSIOLOGICAL OPTICS

Light, Colour and Vision

By Prof. Yves Le Grand. Approved translation by Dr. R. W. G. Hunt, Dr. J. W. T. Walsh, and F. R. W. Hunt. Pp. xiii+512. (London: Chapman and Hall, Ltd., 1957.) 63s. net.

THIS book is a translation of Vol. 2 of Prof. Le Grand's "Optique Physiologique", and the first word must be one of congratulation to the team of translators. They have done a first-class job, as we might indeed expect they would, and they can derive much satisfaction from the fruit of their very considerable labours. There has evidently been close and cordial co-operation between author and translators, and the opportunity has been taken to report work of more recent date than 1948, when the French edition was first published.

The book is essentially a survey of researches on visual perception, with the main emphasis on colour vision. Comparison with Helmholtz's "Physiological Optics" is suggested on the jacket, but perhaps a more valid parallel would be with Parsons's "Colour Vision". Certainly, Sir John would have rejoiced, if he had lived a few weeks longer, to have seen the publication in Britain of this worthy successor to his own book, which was itself a landmark in the development of the subject.

The contents are divided into two Sections, with Section *A* headed "Experimental Facts", and Section *B* "Theories of Vision", but the merits of this division are not too clear. Thus, of the five chapters comprising Section *B*, three of them deal with the anatomy, the photochemistry and the electrophysiology of the retina respectively, and are primarily factual rather than theoretical. On the other hand, in the fifteen chapters comprising Section *A*, covering radiation, photometry, colorimetry, normal and anomalous colour vision, thresholds of various sorts, and spatial and temporal effects, a number of theoretical tit-bits have crept in.

One of the most effective of these is on p. 271, where the author discusses Fechner's integration of discrimination steps to produce a scale of sensation *S*. He concludes that "it may be questioned whether there is any reality in this quantity *S* which has lost all the attributes that are needed for a scale of constant intervals and that were assigned to it by Fechner in order to define it". In spite of this denunciation, the logarithmic relation between stimulus and sensation will no doubt continue to plague us for many years to come.

Le Grand's balanced account of colour vision theories does not conceal the fact that he himself is a Young–Helmholtz 'three-components' man and he regrets the disfavour into which Young's theory has undeservedly fallen among certain physiologists. Of the zone theories which are an elaboration of Young's theory, he recognizes that they may correspond with physiological facts, but that only experiment can confirm or deny this. He also reminds us that whatever the retinal basis for colour discrimination may be, the identification of the messages between retina and brain, and their decoding in the brain, have still to be explained.

Occasionally, Le Grand's judgment seems to falter, as when he suggests on p. 287 that all colour threshold problems can be solved from the discrimination ellipses in the chromaticity chart. Again, the manner in which on p. 302 he brushes aside after-images as an annoyance to the physicist, apparently unworthy of his study, is somewhat out of keeping with the general tenor of the book. Then his reference on p. 336 to the experiments by Horner and Purslow, in which the size of field was found to affect the red-green mixture required to match a yellow in the Nagel anomaloscope, does not explain that their observations were made with an unrestricted natural pupil and with the observer stationed at various distances from the anomaloscope field. The phenomenon is of very real interest, but it seems to be connected more with the pupil diameter than with the size of field, since the same effect is not observed with an instrument using an artificial pupil.

But these are minor criticisms of what is undoubtedly a very fine book. It is written by a physicist who has himself made notable original contributions, both theoretical and experimental, to the subject of vision, and who has taken a keen interest in its historical background. Above all, he brings out the mystery which still surrounds most visual problems and which adds so much to their attraction. For their complexity and inherent scientific interest, they compare favourably with the problem of launching a *sputnik*, their study is far less expensive and their solution is happily not a matter involving national military prestige. W. D. WRIGHT

Organic Reactions

Vol. 9. Edited by Roger Adams, A. H. Blatt, Arthur C. Cope, David Y. Curtin, Frank C. McGrew and Carl Niemann. Pp. viii+468. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1957.) 96*s*. net.

EVERY new volume in this series, which began in 1942, receives a warm welcome from research workers, teachers, and advanced students concerned with reactions capable of wide application in organic chemical synthesis. Many such reactions find repeated mention in text-books and laboratory manuals of organic chemistry; but usually such references are confined to a specific application, give no general survey of the scope of the process concerned, and fail to indicate its limitations, disturbing influences, and variations of practical technique. These omissions are fully met in "Organic Reactions", every volume of which contains a series of chapters each devoted to a single reaction, or sometimes to a definite phase of a reaction, of outstanding synthetic importance.

The seven chapters of the present volume, written, as usual, by workers actively engaged in the several fields, deal with the cleavage of non-enolizable ketones with sodium amide, the Gattermann synthesis of aldehydes, the Baeyer-Villiger oxidation of aldehydes and ketones, the alkylation of esters and nitriles, the reaction of halogens with silver salts of carboxylic acids, the synthesis of β-lactams, and the Pschorr synthesis and related diazonium ring-closure reactions. The account of the alkylation of esters and nitriles is by far the longest of these contributions: discussions of mechanism, scope, methods, and experimental conditions, are supplemented by twenty tabulated summaries giving the alkylating agent, product, yield, and base for an extensive variety of specific esters and nitriles. This chapter alone contains more than a thousand references to the original literature; and, in general, the work is admirably documented and indexed. JOHN READ

Mathematics and Statistics for use in Pharmacology, Biology and Chemistry

By L. Saunders and R. Fleming. Pp. x+257. (London: The Pharmaceutical Press, 1957. Published by direction of the Council of the Pharmaceutical Society of Great Britain.) 27*s*. 6*d*.

THE authors have attempted to provide a course adequate for honours students in pharmacy whose mathematical knowledge is slight. Early chapters summarize the elementary rules of indices and logarithms and principles of algebra and graphs. Differential and integral calculus, trigonometry, and differential equations are all covered within 110 pages. Apart from some carelessness of phrasing, such as describing a determinant as an operator, the text seems sound, though naturally without mathematical rigour. Whether it could in fact be understood by the students for whom it is intended is more doubtful; it seems more likely to be of service to graduates who have previously studied mathematics more thoroughly but who need a much-condensed revision course.

The second half of the book is concerned with probability and statistics, and is less satisfactory. The text is marred by a number of wrong or misleading statements about populations and samples, expectation, degrees of freedom, and other fundamental ideas. It is difficult to imagine these chapters as adequate even for revision purposes, although the extent of the statistical methods that the authors regard as important for pharmacists is encouraging. The final chapter on quality control and acceptance sampling of pharmaceutical products and errors of dispensing is by far the most interesting in the book; this certainly deserves careful study, and could usefully be developed more fully. D. J. FINNEY

The Support of Medical Research

Edited by Sir Harold Himsworth and J. F. Delafresnaye. (A Symposium organized by the Council for International Organizations of Medical Sciences.) Pp. xi+170. (Oxford: Blackwell Scientific Publications, 1956.) 17*s*. 6*d*. net.

THIS book is a report of a conference which the Council for International Organizations of Medical Sciences held in London late in 1954 under the joint auspices of Unesco and the World Health Organization. The meeting was well attended, and provided the participants with an opportunity for informing each other how research councils and similar institutions operate in their respective countries. It also made possible the statement of views on the desirability of medical research in universities being financed both directly out of university funds and out of subventions from outside bodies, such as the Medical Research Council in Great Britain. The several ways by which central research organizations can support medical research were also discussed, as was the training and recruitment of medical research workers. Appendixes to the book provide brief accounts of the arrangements for medical research which exist in the countries represented at the conference.

Buried Treasure

By Paul Johnstone. Pp. iii+67 plates. (London: Phoenix House, Ltd., 1957.) 16*s*. net.

WITHOUT doubt the television programmes on archæology, organized by Paul Johnstone, have much increased the general interest in the subject. His advisory panel has consisted of experts in the various aspects of the study with the result that viewers have had of the best and not merely second-hand material. The book under review is an account by Johnstone of the various programmes he organized. Piltdown was long supposed to be the earliest human skull found; the exposure created a stir which spread well beyond purely scientific circles. It was right that the story of Piltdown and its true significance should be given in the first chapter. But though Piltdown has had to go, there still remains *Australopithecus* in South Africa, and it is logical that a study of this early creature should follow. The earliest appearance of art and how the artists worked continues the story into late Pleistocene times. Accounts of Jericho, the neolithic stone temples in Malta, Stone Age house building, and the great West Kennet Long Barrow come next; and this leads on to a description of the recent work done at our greatest stone monument of all, Stonehenge. Finally, there are chapters on the Etruscans, on the Gaulish finds at Châtillon-sur-Seine, on Maiden Castle near Dorchester, and on the discoveries made in the Tollund peat bog in Denmark of the well-preserved body of a prehistoric (Iron Age) man. The book is richly illustrated, and there is a short bibliography.

M. C. BURKITT

DR. IRVING LANGMUIR'S CONTRIBUTIONS TO PHYSICS

By DR. ALBERT W. HULL
General Electric Co., Schenectady, New York

SIR ERIC RIDEAL'S excellent tribute to Dr. Irving Langmuir (*Nature*, **180**, 581; 1957) emphasizes, very properly, his contributions to chemistry. To those of us who had the privilege of working with him, Dr. Langmuir was unsurpassed also as a physicist; and could equally well have received the Nobel Prize for his contributions in physics.

Sir Eric has mentioned Langmuir's study of the loss of heat from electrically heated wires in gases. This had been the subject of his Göttingen Ph.D. thesis—a very unexciting subject, but see what it led to in his hands! On coming to the General Electric Research Laboratory, he was quick to grasp the opportunity afforded by Coolidge's development of drawn tungsten wire, and spent the first three or four years carrying heat-loss studies to higher temperatures. At one point Dr. Whitney, director of the Laboratory, had to defend Langmuir before the board of directors, who thought he was wasting his time. "You leave Langmuir alone," Dr. Whitney said; "he is doing good work." The results proved it.

One of these results was his equation for heat loss, which he represented as conduction in a stationary film around the wire, with convection outside this film. In discussing this equation with him soon after its publication, I commented that the mechanism seemed artificial. He made the excellent reply: "What difference does it make, provided it gives the right result?"

Shortly thereafter he justified this theory by calculating, and then demonstrating experimentally, that the loss of heat from a lamp filament in nitrogen at atmospheric pressure could be made even less than in vacuum by coiling the wire in a tight helix, thus effectively increasing its diameter and hence the thickness of the 'stationary' film.

It was inevitable that Langmuir should observe a deviation from this equation in the case of hydrogen, namely, a large increase of heat loss above 2,200° C. This he explained correctly as due to the dissociation of the hydrogen into atoms. It was several years later when, in response to a letter from R. W. Wood, asking why a platinum wire in a remote part of a tube carrying a glow discharge in hydrogen should become white hot, Langmuir answered at once, "Association of hydrogen atoms to molecules at the wire". Thinking of this, Langmuir reasoned that if the dissociated hydrogen from an arc discharge were blown against a metal a great deal of heat could be delivered to it—the hydrogen welding torch.

Langmuir's interest in tungsten filaments led him, in 1912, into electronics, the field that was to prove so fruitful in his hands. Several years previously, O. W. Richardson had published his famous equation of electron emission. Langmuir noted that this equation predicted for tungsten, near its melting point, an electron emission of several hundred amperes per square centimetre. He tried it, and found not amperes, but only milliamperes. The emission followed Richardson's equation only up to a certain temperature, above which it became saturated and depended only on voltage. I happened to be visiting Langmuir when he made this discovery—I was teaching at the time. He described fully his experiments, with none of the secrecy that was not uncommon at some places at the time, and said: "It should be possible to apply Poisson's equation to this". He did, and the result was his famous law of electron space-charge, which became the basis for the great electronic tube developments that followed. He devoted considerable time to the calculation of accurate space-charge formulæ for cylindrical and spherical electrodes, and the voltage gradient in electron tubes, including the important voltage minimum resulting from the initial velocities of the electrons.

Early in his electron-emission studies Langmuir noted an enormous increase in electron emission when he used, instead of pure tungsten wires, the 'thoriated tungsten' lamp wire, to which ½ per cent of thorium oxide had been added to prevent large crystal growth and 'off-setting'. The observation itself was a tribute to his careful vacuum technique, in this case the immersion of the entire tube in liquid air to avoid contamination by water vapour from the glass. But his explanation of it is a marvellous example of his insight into physical phenomena. He visualized, and proved, that the thorium oxide is partially dissociated by the tungsten, releasing thorium atoms which diffuse to the surface and form a strongly adherent monatomic film, of lower work function than tungsten metal. These thoriated tungsten filaments are standard components of to-day's medium-power tubes.

A key feature of Langmuir's early research was good vacuum. The pumps available were clumsy and slow. In 1915, W. Gaede published an article on his 'diffusion pump'. Langmuir at once concluded that the action of this pump was not diffusion, but mechanical transport of the gas by mercury vapour atoms. He proceeded to design a high-speed 'condensation pump', in which a large blast of mercury vapour sweeps the gas before it, and then condenses on a water-cooled wall and runs back to the boiler. All high-speed high-vacuum pumps used in electronics and nuclear physics to-day embody this principle.

In 1922 Langmuir turned his attention to low-pressure gas discharges. He predicted and proved experimentally that a negatively charged electrode in a gas discharge is surrounded by a 'positive ion sheath', containing positive ions but no electrons; and that an insulated electrode must charge itself negatively, sufficiently to repel all but a small fraction of the electrons moving toward it; the amount for mercury vapour being 7–16 V., depending on the pressure. This showed that all previous measurements with probe electrodes had been in error by amounts of this magnitude. He then demonstrated, in a series of brilliant experimental studies, two correct methods of measuring potential in a discharge, one using a heated electrode, the potential of which is adjusted until the electrons emitted by it are just able to escape; and the other a 'kink' in the semi-logarithmic plot of the volt-ampere characteristic of a cold probe. These methods have become standard procedures.

His quantitative theory of the positive-ion sheath showed why a negative voltage on the grid of a thyratron cannot interrupt the discharge, since each grid wire is surrounded by a thin positive-ion sheath that insulates it from the discharge.

He explained correctly the increase of pressure toward the anode end of a tube as the reaction of the oppositely directed momentum delivered to the glass walls by the positive ions.

Langmuir's classic studies of the adsorption of cæsium on tungsten, begun in 1923 and carried on intermittently for fifteen years, are a beautiful example of the combination of physics and chemistry in a pioneer investigation. The experimental part was physics, an extended series of measurements, first with K. H. Kingdon and later with J. B. Taylor, of the electron and positive-ion emission from tungsten wires in cæsium vapour. He predicted and verified experimentally that at high temperatures, where the work function of the clean wire (4·6 V.) is greater than the ionizing potential (3·9 V.) of the vapour, every cæsium atom that struck the filament left it as a positive ion; but that below 1,100° K. no positive ions were formed, because the fraction of the surface of the wire that was covered with cæsium reduced its work function below 3·9 V. Also that there was no positive-ion emission from a thorium-coated thoriated tungsten wire, the work function of which is 3·1 V.

The chemical part of the investigation included the use of a suitably modified form of the Saha equation for thermal ionization of a gas; and an adaptation of Gibbs's equation of state to two dimensions. With this powerful approach he predicted accurately not only the emission of electrons, ions and atoms as a function of temperature and density of adsorbed atoms, but also the spreading force of these 'adatoms', their heat of evaporation and the contact potential of the partially coated filament.

One more example of Langmuir's powerful, yet simple, application of physical laws was his calculation of the light-scattering power of 'white' smoke as a screening agent. Having previously developed, in his icing studies, a method of measuring particle size, he calculated from Rayleigh's law of scattering the optimum size of particle; and then, with V. J. Schaefer, produced particles of this size, with a screening power per gallon of oil many thousands of times greater than the black smoke then in use.

A final contribution, completed shortly before his death, was an exhaustive mathematical study of the probability of induced rainfall produced by periodic seeding of clouds with silver iodide.

I cannot conclude without an affectionate personal tribute to Irving Langmuir, as a loyal friend and stimulating colleague—inadequate words—to whose inspiring influence I owe a very great deal.

THE GEOLOGICAL SOCIETY OF LONDON

By Dr. W. CAMPBELL SMITH, C.B.E.

EARLY in 1807 a small group of men actively interested in mineralogy had been brought together by Dr. William Babington for meetings at his house. Several of these men had been members of the British Mineralogical Society (1799), which in 1806 had been incorporated with the still earlier Askesian Society.

This little group, with others, making thirteen in all, primarily interested in mineralogy but recognizing the need to learn about the wider fields of the then new science of geology, became the founders of the Geological Society of London. The meeting at which the Society was founded was held at the Freemasons' Tavern in Great Queen Street on November 13, 1807.

At the second meeting the Hon. C. F. Greville was invited to become patron, Greenough was elected president, and honorary members were elected from distinguished men of science in the British Isles. The honorary members numbered forty-two, of whom five were foreigners. Foreign members as such were not instituted until 1814. Among the first of these, elected in 1815, were Leopold von Buch, Cuvier, Haüy and Werner. Baron Humboldt was elected in 1817.

Six of the thirteen founders were Fellows of the Royal Society. These were Babington and Bournon, William Allen, founder of the firm of Allen and Hanbury, Humphry Davy, then secretary of the Royal Society, G. B. Greenough, a pupil of the celebrated Werner at Freiberg, and W. H. Pepys.

The new Society grew rapidly, and the lists of members elected in the early years are full of names now famous in science: W. H. Wollaston joined the Society in 1812, William Buckland in 1813, Sedgwick in 1818, Lyell in the following year, and Murchison and Faraday in 1824. Charles Darwin, persuaded thereto by Lyell, was secretary during 1838–41 and, coming to rather later days, T. H. Huxley during 1859–63.

A royal charter had been applied for in 1824 and was granted on April 23, 1825. There were then 372 elected members, of whom 260 were resident in or within twenty miles of London. The class of honorary members ceased with the charter. Except for a decline around 1857, after the Crimean War, there was a steady rise in the fellowship to 1,361 in 1881, after which numbers fell a little, reaching their lowest in 1942 (1,067). Thereafter there has been a steady rise to the present figure of 2,326 in 1957. This considerable increase may be attributable partly to the increased interest taken in geology in all the universities and its increasing application in some industries; it is also a result of efforts of the Council to make the Society more useful to geologists, prompted thereto by the suggestions made by three of its recent presidents.

There have been few changes in the rules for Fellows and Foreign Members. A new class of Foreign Correspondents, from which Foreign Members were elected, was made in 1863, but discontinued in 1946. Women Fellows were not admitted until 1919, although proposals to this end had been made in 1889, and again in 1907 and 1909, and this in spite of the fact that many women geologists had made important contributions to the science, as indeed the Society had publicly recognized by various awards since 1893. A new class of Junior Associates was instituted in 1944 for men and women students of geology not less than eighteen and not more than twenty-three years of age.

The Society was very active from the start. Committees were set up to arrange the collection of minerals, to arrange for a uniform nomenclature, to prepare and collect mineralogical maps, models and sections of mines, and to approve communications previous to their being read before the Society.

The collection of minerals, rocks and 'extraneous fossils' grew rapidly and was of great use to the members. Its use particularly as regards British fossils was later superseded by the collection in the Museum of the Geological Survey, founded in 1835. Much work had been expended on arranging and cataloguing the Geological Society's collection by a succession of able and enthusiastic curators. A list of all the type-specimens was prepared by C. Davies Sherborn between 1891 and 1899, and a catalogue based on this list and edited by J. F. Blake was published in 1902. By this time the Library, which is one of the best in its field, was needing more space and in 1911, to make room for the books, the Society's collections were presented to the British Museum (Natural History) and the Geological Survey.

The Committee of Maps, appointed in 1809, does not seem to have been very active; but G. B. Greenough, first president of the Society, had started work on a geological map of England as early as 1808. This he presented in 1812; and it was published by the Society in 1820. The cost of drawing and engraving alone was £1,300.

It seems strange that the Society embarked on the preparation of this map, as it must have been known that William Smith had a geological map in hand. He was neither a member nor an honorary member of the Society, and he seems to have been almost ignored. However, the Society did something later to make amends for its early neglect of the 'father of English geology'.

W. H. Wollaston, who died in 1828, left the Society £1,000 to create a donation fund to aid or reward the researches of any individual or individuals of every country. The first use made of this fund was to strike a medal and to present the first Wollaston Medal to William Smith, together with the proceeds of the donation fund. Much later still, an annual William Smith Lecture was instituted. The first of these was given by W. W. Watts in 1945.

Other medals were founded much later: the Murchison (1871), Lyell (1875), Bigsby (1876), and at a still later period, the Prestwich Medal (1896). A fund was founded in 1876 by H. C. Barlow in honour of Prof. Robert Jameson, of Edinburgh. Many other bequests have been made for the encouragement of research in geology or for assistance in travel or with publications. They bear the names of the benefactors: Blanford, Daniel Pidgeon, Fearnsides, Garwood, Gloyne, Greenly, J. B. Tyrrell, Henry Woods and R. H. Worth; the last fund is especially for the encouragement of amateur geologists.

In 1945, the Anglo-Iranian and Burmah Oil Companies agreed jointly to place at the disposal of the Society a sum of money to be used to promote each year a geological tour for university students. The first of these tours was undertaken in 1946.

Apart from this, the Geological Society has not undertaken the organization of geological excursions. To the great benefit of all geologists this work was taken thoroughly in hand by the Geologists' Association, founded in London in 1858.

Quite early in its history the Society began publication of selected papers in the *Transactions*, 1811–56. These were in quarto and were profusely illustrated. There were long delays in printing the *Transactions*, and, in order to achieve a speedier reporting of papers read and of other geological news, *Proceedings* were published. These were first issued in 1826, but were discontinued in 1846 in favour of the *Quarterly Journal*, commenced in 1845 and now in its 113th volume. The present "Abstract of Proceedings", issued after each meeting, is a slightly modified form of the Abstracts first circulated to Fellows in 1857. The Society is now about to start a new publication of *Memoirs*. This new venture has been made possible by a generous bequest under the will of the late Henry Woods.

Meetings at which the results of geological research have been communicated and discussed have been, and still are, the most important activity of the Society. The earliest meetings of the Society were held at the Freemasons' Tavern, the members dining together before the meeting. Rooms were rented successively in Garden Court, Temple, and Lincoln's Inn Fields; but it was not until 1816, when rooms were taken at 20 Bedford Street, that a suitable meeting room became available. In 1828, apartments at Somerset House were granted to the Society, and there the Society remained until the move to its present rooms in Burlington House in 1874.

The practice of members dining together before the meeting continued for some years, and in 1824 the Geological Society Club was formed as a dining club limited to forty members. This Club still continues, but the hour of the Society's meeting was changed in 1915 from 8 to 5 o'clock; so the Club now dines after the meeting instead of before.

The centenary of the Society in 1907 was celebrated with great ceremony, and its proceedings are recorded in the centenary volume published in 1909. In preparation for the centenary, a history of the Society was written by Horace B. Woodward. There the real history of the first hundred years of the Society is told, and in it is recorded how the meetings of the Society have witnessed the gradual growth of the whole of geology from its beginnings. It is difficult in a few words to give any adequate account of the contributions Fellows of the Society have made to their science in the past fifty years, and what follows is the merest sketch.

One can recall now classic papers on the structure of the Highlands, cauldron subsidences and ring intrusions with their accompanying cone-sheets and dyke-swarms; great papers on the Lake District, and on glaciation; the geology of almost the whole of Wales worked out by perhaps a dozen different authors. In palæontology one recalls the papers on ammonites and the detailed zoning of the Jurassic; non-marine lamellibranchs and zoning of the Coal Measures; the flora of the Kent Coalfield; the analysis of the Pliocene flora based on the study of fossil seeds, and the later technique of pollen analysis.

Memorable papers dealing with metamorphic and volcanic rocks have greatly advanced our knowledge of these branches of petrography; and discussions on differentiation, assimilation and the more recently advanced theories on the formation of granite may have been almost as animated as some of the early discussions of the previous century.

Wegener's theory of continental drift was the subject of a discussion in 1935; rostro-carinate flints and eoliths was another subject discussed before a large audience; and, one must admit it, the most crowded of all the meetings were those in 1912 and 1913 when fragments of the Piltdown skull and the broken lower mandible and canine tooth were described.

New techniques have been introduced to the Society both as papers and as exhibits. The use of cellulose films in the study of plant remains, applicable also to graptolites and corals, in 1923 and again in 1928; the use of polarized light for the study of the minute structure of foraminifera was demonstrated in 1920; and still earlier (1917–18) the use of X-rays for a similar purpose. Another war-time paper read in February 1915 was on radioactive methods of determining geological time, and a great meeting in 1923 was Joly's lecture on the bearing of some recent advances in physical science on geology; a development from his much earlier published book, "Radioactivity and Geology".

In the early days of the Society the main interest of its members was in minerals and mines, but they soon turned their attention to the wider fields of geology and to stratigraphy. The charge that the Society has too much neglected the economic applications of geology has perhaps been justified, but there is ample evidence now of its active interest in the practical problems of the day. A lecture and papers on oil in Britain, and a discussion in 1933 on the falling water-level in the Chalk under London, attracted crowded audiences. Many papers have dealt with the constitution of coal and the structure and zoning of the coal measures, and recent methods of geophysical survey and results that have been deduced from them have been the subject of several papers in the past ten years.

There are plenty of papers and material for interesting lectures, and the lecture room at Burlington House is often crowded to capacity. The problem that faces the Society is certainly not a lack of new fields of inquiry but rather perhaps how to extend its scope and bring to the Fellows more papers on the geology of other lands. The more material needs are: space for its audience, shelves for its books, and money for its printing. Reluctantly it has at last had to raise the annual subscription to meet the rising costs. Financing printing is, however, only half the solution; the remaining problem is the ever-present one of how to persuade authors not to write until their work is as complete as they can make it, and, when they write, to aim at brevity as well as clearness in expression and condensed presentation of essential details. This was the plea of three successive presidents in the 'eighties. It is still the plea of the Society to-day.

The 150th anniversary of the foundation of the Society was celebrated on November 13, 1957, and was marked by an afternoon meeting at which the president, Dr. Leonard Hawkes, gave a brief address, followed by the thirteenth William Smith Lecture, given by Prof. C. E. Tilley. A conversazione was held in the evening in the rooms of the Royal Society and in the Geological Society's apartments. Exhibits arranged by Fellows, many university geology departments, oil companies, the Geological Survey of Great Britain, and the overseas Geological Surveys, illustrated recent progress in geology.

NUTRITIVE VALUE OF PROTEINS

The 112th meeting of the Nutrition Society was held on October 12 at the Royal Free Hospital School of Medicine, London, and took the form of a symposium on "The Nutritive Value of Proteins", with Dr. D. P. Cuthbertson, director of the Rowett Research Institute, Aberdeenshire, in the chair.

In his opening remarks, the chairman first pointed out that the quality and quantity of our protein needs are ever present in our daily speculations of what we shall eat and wherewithal we shall be clothed, and these in turn are largely governed by the kind of food our farm animals eat. The quality of the protein in the concentrated part of the diet or ration can in some cases be enhanced by proper processing, but it is sometimes damaged. Britain's annual imports of animal protein feeding stuffs amount to 1,048,000 tons and cost £38,129,000 a year, and a considerable saving on this could be effected by avoiding damage to the nutritive value not only of these imports but also of home-produced concentrates during processing and storage, and by their proper use to balance the ration.

The problems of protein quality and quantity for animals, including man, are of importance not only to the United Kingdom as one of the world's largest importers, but also to such bodies as the Food and Agriculture and World Health Organizations. For these need to know the nature and amount of the protein-rich supplements—milk, fish, soya-bean, groundnut preparations and so on—which should be added to a basic cereal or starchy diets in order to prevent protein malnutrition and to achieve some minimum standard of adequacy.

Dr. Kathleen Henry (National Institute for Research in Dairying), in a joint paper with Dr. S. K. Kon on "The Nutritive Value of Proteins: General Considerations", pointed out that earlier concepts of nutrition divided proteins into those of first- and those of second-class quality, the former being of animal and the latter of vegetable origin. With increasing knowledge it became evident that the differences between foods as protein sources reflect differences in amino-acid composition and also that the superiority of 'first class' protein is often partly due to accompanying vitamins. We know that the distinction between animal and vegetable proteins is neither rigid nor always justified.

The value of a food as a source of protein is determined by the concentration of protein in it, the digestibility of the protein, the availability of its amino-acids for the synthesis of tissue protein, and its amino-acid pattern, particularly the content and proportions of the essential amino-acids. Digestibility and amino-acid pattern in turn determine the value of the food protein to the animal. There exist now many biological methods of assessing a protein on this basis, most of which compound these variables into one numerical expression. All are designed for, and capable of, assigning to a protein a relative order of nutritional merit and thus all can be considered as measuring its biological value.

Normally, proteins are considered in relation to their ability to promote growth or repair of body tissues or both. A protein that may be adequate for repair and maintenance in an adult animal may be less satisfactory for the combined functions of growth and repair in the young. Furthermore, the value of a protein for certain functions, such as replacement and building of specific plasma proteins, hæmoglobin and enzymes, may be quite different from that for the repair of body tissues as a whole.

Dr. Henry then dealt with the amino-acids essential for different species and at different ages, and the need both to secure that the amino-acids are present in the correct proportion, and to satisfy the energy requirements for maximum utilization of protein. She also dealt with mixed diets, the supplementary effect of proteins and the timing of their administration. It was stressed that the assessment of quality from amino-acid composition requires confirmation from feeding experiments. The effects of heat treatment were considered briefly in relation to culinary needs, elimination of toxic effects and preservation.

"Biological Methods of evaluating Protein Quality" was the topic of a paper by Dr. A. E. Bender (Bovril, Ltd.). He stressed the need to realize the nature of the conventional tests for protein quality and to appreciate the significance of the results derived from them. He dealt first with the methods of assay: the screening tests to give approximate grading, the protein efficiency ratio for growth, the net protein retention, the rat-repletion method and the microbiological technique. Next, Dr. Bender dealt with quantitative measurements, the Thomas–Mitchell method which measures the percentage of the absorbed nitrogen retained in the body and is termed the 'biological value', the 'nitrogen-balance index' introduced partly to avoid measuring endogenous excretion required in the preceding method, the carcase-nitrogen method which may involve only a simple water determination, the 'egg-replacement value' used mainly in human experiments, and growth and nitrogen balance methods. Various indirect methods were also outlined.

What is often required, however, is an experimental version of a field test, and here the gross protein value test has proved very useful. The diet is based on the normal practical diet of cereal, fed at 8 per cent protein-level, supplemented with 3 per cent test protein. The diet thus simulates husbandry conditions in which a knowledge of the nutritive value of the combination is required rather than the biological value of the concentrate alone. The gross protein value is the extra growth produced (beyond that on the control ration) divided by the supplementary protein eaten in a two-week experiment.

All measures of protein quality are essentially a function of the limiting amino-acid: the tests yield no information about the other amino-acids. The 'biological value' or the 'protein efficiency ratio' are not complete descriptions of a protein, since it is possible to find two proteins with the same biological value but with differing amounts of the non-limiting essential amino-acids.

Dr. K. J. Carpenter (School of Agriculture, Cambridge) then dealt with "Chemical Methods of evaluating Protein Quality". He stressed the impossibility of devising a single test (chemical or biological) that will give the answer for all circumstances. Analysis for amino-acids takes too much time and gives no information about digestibility or availability. A number of quick laboratory tests have been developed for foods to answer the needs of specific industries.

Of the cereals, only maize has been shown to be of variable protein quality, and that appears to be inversely related to the nitrogen content. Baking has little effect on quality, but the processing of breakfast foods may be deleterious.

Taking soya-bean oil meal as the principal example of the oil-seed meals, Dr. Carpenter pointed out that it requires some heating to destroy a trypsin inhibitor and so attain maximum value. The destruction runs parallel to, and may be followed by, the fall in urease activity. Heating beyond this maximum damages protein quality. Solubility tests carried out directly on the meal will give a measure of this damage; they are not effective with enzymic digests prepared from the meal. The enzymic release of specific amino-acids (estimated microbiologically) points to the 'locking-up' of lysine in overheated samples. Formol-titration similarly reflects damage by following the reduction of free ε-NH_2 groups, particularly that of lysine. In cotton-seed meal, quality control is complicated by the toxicity of the gossypol present and its apparent interaction with protein quality.

Animal products used in animal nutrition—fish and meat meals—present special difficulties because, in addition to changes induced by varying processing, the amino-acid composition of the raw material may vary considerably.

Animal products are rated highly because of their high concentration of nutritionally available lysine. As for the oil-seed meals, heat damage reduces the availability of the lysine. On the hypothesis that lysine is nutritionally available only when its terminal NH_2-group is free, a recently developed method measures 'available lysine' as the dinitrofluorobenzene derivative. The results obtained with a series of fish, whale and meat products have shown a close correlation with corresponding results from chick-feeding tests under conditions that emphasize the lysine contribution of the test materials.

The sulphur amino-acids are possible alternatives to lysine as the limiting amino-acids. Dr. Carpenter hoped that processing damage to lysine and cystine (more susceptible than methionine) might be roughly parallel, though the presence or absence of oxygen may upset this.

Dried milk, the product of a very even raw material, is exceptionally subject to processing damage; the dinitrofluorobenzene method and microbiological assay of an enzymic digest gave parallel rating of quality. For the evaluation of mixed diets this latter method was thought to be the most effective.

"The Importance of Protein Quality in Animal Feeding" was described by Dr. Gabrielle Ellinger (Rowett Research Institute). Economy in the use of protein may be exercised by the correct allocation of concentrates to practical rations, and by the conservation of quality during the production of concentrates.

Currently, practical rations for non-ruminants are compounded to contain protein in excess of requirement to compensate for the fluctuations in the quantity and quality of protein in available feeding stuffs.

To have practical significance, the evaluation of concentrates must be for their capacity as supplementary protein. The cereals, used principally as sources of energy for fowls, contribute 40–65 per cent of the total protein in some practical rations according to the classes of poultry concerned. Similarly, in pig rations 50–70 per cent of the protein is derived from cereals according to the proportion of millers' offals and bran included. Related to the chick's and pig's requirements for the essential amino-acids, the proteins of wheat, barley, oats and maize are deficient mainly in lysine and rather less deficient in the sulphur amino-acids. Maize is also deficient in tryptophan. No processing damage is involved, although feeding quality of maize is known to vary with variety and fertilizer treatment.

Beyond the quantitative supplementation of the cereal proteins, therefore, concentrates must compensate for the failure of cereal proteins to contribute their share of the essential amino-acids. The concentrates that are offered as feeding stuffs may be derived from a wide range of raw materials and differ greatly in their amino-acid composition. Processing damage introduces further variations in the protein quality of any given concentrate. Lysine and the sulphur amino-acids are not only the acids most subject to damage but also, being the limiting amino-acids in the cereals, their concentration largely determines the supplementary value of the concentrates.

The critical level of protein in the test rations must be considered in relation to the energy content. The highest critical level of protein at which additions bring no improvements and reductions a fall in production is in itself a measure of protein quality, and has been used for grading certain concentrates as supplements in pig rations. Alternatively, in the gross protein value experiments, concentrates fed at a constant and very low level of protein contribution and compared with standard protein have been effectively graded according to the heat damage sustained. A concentrate fed for its contribution of a particular amino-acid may be evaluated in terms of the availability of that acid.

Prof. B. S. Platt and Mr. D. S. Miller (Human Nutrition Unit, Medical Research Council), in their paper on "The Quantity and Quality of Protein for Human Nutrition", reviewed some of the findings of earlier workers in this field which are too frequently neglected. They also directed attention to the more recent Princeton Conference on Human Protein Requirements and their Fulfilment in Practice and to Terroine's emphasis on the distinction between physiological requirement—the minimum amount of protein required to maintain nitrogen balance—and the hygienic requirement—the amount needed under the stresses of everyday life.

Many of the difficulties of prescribing a diet for the human subject are concerned with (*a*) the complexity of the mixtures eaten by man; (*b*) the nature and timing of snacks and meals; (*c*) the effect on food values of a wide variety of methods of processing, including cooking; (*d*) the level in the diet, not only of protein but also of other sources of energy—fats and carbohydrates—and of various vitamins and minerals; and (*e*) the balance between the proteins and several other dietary factors. In some human dietaries, better protein utilization might be achieved by providing additional amounts of either fat or carbohydrate or both, thereby not only preventing wasteful burning of protein but also inducing a protein-sparing action. We do not know whether the pattern of amino-acid requirements is the same for maintenance as for growth of the young or, therefore, whether there are additional needs of the mother during pregnancy and lactation. However, the validity of the methods for the determination of the physiological requirement of an individual for a specified protein or for the essential amino-acids is fairly well established, although it is still not understood, for example, (*a*) why in Rose's experiments it was necessary to have such a high calorie intake; (*b*) why the ratio of infant to adult requirements per kilogram of body weight is so much higher when expressed in terms of essential amino-acids (about 10 : 1 for most amino-acids) as compared with the ratio in terms of reference protein (about 5 : 1); (*c*) what the composition and amount in a diet of nitrogenous matter other than the essential amino-acid nitrogen should be; and (*d*) what determines the variations in physiological minima for nitrogen for different individuals. The importance of zymotic factors in the production of protein malnutrition has not yet been fully appreciated.

Possibly for maize and most certainly for cassava pap, the volume of the infant stomach must be a limiting factor in adequate protein nutrition of the young child. The necessity in these circumstances of providing food rich in protein is clear; this may be most conveniently and desirably provided as human milk, but where the diet is low in protein the problem of extra supplies of good protein is simply shifted to the mother who can, however, utilize cruder sources of supply than can the young child.

The final paper of the session was on "Nitrogen Balance following Injuries" by Dr. J. P. Bull (Medical Research Council, Industrial Injuries and Burns Research Unit, Birmingham). Dr. Bull pointed out that the circumstances, nature and timing of injury and the corrective procedures are sufficiently different to make one cautious in accepting an operation as a very close analogy to accidental trauma. In the latter Dr. Bull considered that the overall nitrogen balance is not entirely informative when one considers losses of whole protein, as in exudate or hæmorrhage and transfusions of similar materials on the same basis as oral feeding and urinary and fæcal losses. There is no possibility of an initial stabilizing period in accident cases, and the previous nutritional status cannot be known with precision. In the more severe injuries, therapy must necessarily be varied to meet individual requirements; nutrition is only one of these, and must be changed to permit other procedures.

It has been shown that intravenous plasma protein is only slowly metabolized, and if nitrogen is so given in excess it will be excreted in the urine only after several days. Correspondingly, after transfusion of red cells, excretion of excess nitrogen is even longer delayed. Furthermore, if there has been loss of plasma, as from a burn, or loss of blood from other injuries, intravenous replacement may be virtually direct, so that neither the loss nor the transfusion should appear in the nitrogen balance on the same basis as oral and urinary exchange. Even the quantities accepted for calculation are suspect; digestion and absorption of orally fed protein may well be disturbed in the severely injured patient, and renal excretion of nitrogen is frequently depressed. When one considers the details of the balance sheet within the body, the situation is clearly more complex again. Whatever the overall balance may be, the internal economy of nitrogen is grossly deranged, as shown by changes in plasma proteins.

There appears to be a general increase of catabolism, possibly combined with a diminished anabolism of protein in which adrenocorticotrophin and adrenal cortical hormones may well be playing a part. Prior depletion of protein prevents the increased excretion of nitrogen after injury. It thus seems likely that the more labile protein stores are first used, and when these are exhausted further tissue protein is not raided.

Dr. Bull reported a comparison of nitrogen input with renal nitrogen output in patients who had been adequately treated by transfusion, and found little difficulty in obtaining 'apparent positive' nitrogen balances. Though this clearly does not represent the whole story, it should be remembered that comparison of intake with renal output is the main ground for claims that the 'catabolic phase' makes negative balances obligatory. From this point of view exudate losses should not necessarily be included, since they do not represent catabolism but rather loss of part of an organ equivalent perhaps to an amputation or plasmaphoresis.

Dr. Bull considered that, in the present state of knowledge, the following principles seem rational: (1) Where there are known losses of blood proteins, these should be replaced by transfusion. Plasma and blood are the rational replacement fluids for burns, and blood transfusion for other injuries. Recent studies show that these losses are greater than has previously been assumed, and we are probably only now beginning to obtain adequate correction. (2) Generous protein and calorie supplies should be available for the injured patient in his diet. Many ordinary hospital diets are inadequate in this respect. (3) There is no practical limit to the amount of nitrogen which can be given, either intravenously as hydrolysate or amino-acid mixtures or as oral high-protein tube feeds. It is rational to minimize the loss of nitrogen and to anticipate the subsequent strongly anabolic phase of healing by supplements to ordinary feeding. Inputs of the order of 0·5–1 gm. of nitrogen/kgm. per day and 40–60 Cal./kgm. can be given to the more severely injured patients. (4) In the severely injured patient a multitude of complex processes are at work, and it is presumptuous to expect them to be explained under any single simple theory.

In winding up the symposium, the chairman said that there had been brought to light the need for a clearer definition of terms and a more thorough appreciation of the older literature, which is liable to be forgotten or ignored; that chemical analyses, though useful guides, are not enough by themselves and that the product must, in general, always be tested biologically in the way it will be used; and that there are problems of quality in protein nutrition of man in health, when injured or diseased, that warrant much further study.

D. P. CUTHBERTSON

RETINAL SUMMATION AND HUMAN VISUAL THRESHOLDS

By DR. R. A. WEALE

Visual Research Division, Ophthalmological Research Unit, Medical Research Council,
Institute of Ophthalmology, London, W.C.1

ONE of the mainstays of the duplicity theory of vision is the observation that the centre of the human fovea, which contains only cones, is much less sensitive to light than the extra-foveal regions, dominated by rods. Even at the present time, numerous workers tacitly infer from this finding that, receptor for receptor, rods are very much more sensitive than cones. Observations on dark-adaptation have suggested that the ratio of the two sensitivities may amount to several hundred or even one thousand, and the photo-chemists' apparent inability to extract and characterize cone-pigments goes hand in hand with the view that the low cone-sensitivity is due to the low *in vivo* concentration of these pigments. The plausibility of such an explanation is probably responsible for the fact that experimental evidence not in support of the above views has failed to find acceptance. It may, therefore, be of interest to try to harmonize the two sets of observations and to establish a formal connexion between them.

Lythgoe[1], Stiles and Crawford[2], Craik and Vernon[3], Baumgardt[4] and others have suggested that the large value of the ratio extra-foveal sensitivity/foveal sensitivity may well be due to the good summating properties of the peripheral retinal regions. These would be revealed particularly when experiments are carried out with medium-sized or large test-fields. But as the fovea shows relatively poor summation, visual threshold tests with small fields both in foveal and extra-foveal regions would provide more comparable data than when the fields are large. There is no doubt that this expectation is strikingly fulfilled by experiment. Fig. 1 represents a plot of the logarithm of R_I, the ratio of foveal to extra-foveal thresholds, against the logarithm of A, the size of the test-field, measured in square minutes of arc. Corrections were applied to the measured values for light absorption by the macular pigment, and, where thresholds had been measured with white light, for the non-equality of the energy distribution of the stimulus. The former factor reduces cone thresholds for white-light by approximately 0·1 log unit, the latter increases them by about 0·38 log unit. The resultant correction is small but tends to reduce the scatter of the results. The values of R_I were also calculated so as to refer to the maximum of the spectral sensitivities of dark-adapted foveal and extra-foveal regions, respectively. The letters refer to the authors, and are listed separately in the references. There is an approximately linear relation between R_I and A': extrapolation near the origin

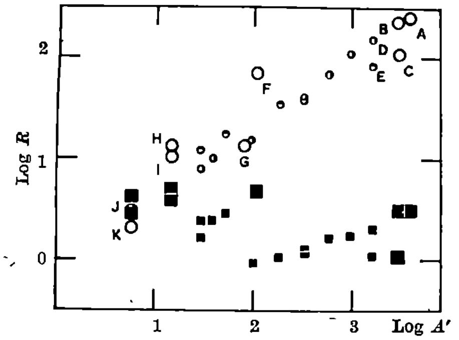

Fig. 1. Log ratio of foveal to extra-foveal thresholds in the dark-adapted human eye as a function of the test-area in log square minutes of arc. Circles: ratios expressed in terms of intensities. Squares: the corresponding values expressed in terms of the 'effective stimuli'. (The letters refer to authors listed in the references)

suggests that, for stimulus areas commensurate with the cross-sectional areas of the receptors involved, R_I approaches unity. This is to say that, when the summating properties of the retina have been eliminated, the sensitivities of rods and cones are approximately equal. Baumgardt[4] reached this conclusion readily from his own results. However, his approximate treatment of the values of R_I as observed with large values of A took no cognizance of retinal summation.

The Effective Stimulus

The concept of the effective quantity of light is of some help in this respect. It has previously been shown[5] to lead to a useful generalization of the Ferry–Porter law, and involves the rejection of light intensity as the almost exclusive factor in stimulus variation. The effective quantity Q is defined as

$$Q = I(AN)^{p} \cdot t^{q} \qquad (1)$$

where A is the retinal area stimulated by light of intensity I and for a duration t; N is the relevant receptor density in the region stimulated, and p and q are the coefficients of spatial and temporal summation, respectively. In the following discussion t^q will be assumed to be constant. The importance of the concept of Q becomes apparent as soon as one considers an orthodox dark-adaptation curve: when a non-fixating human eye is exposed to light, and then left to dark-adapt, its threshold, as measured with, say, a 1°-field, drops rapidly at first, reaches a plateau after some 2–3 min., starts dropping quickly after another 5–7 min., and approaches its final threshold after another 20 min. The first plateau represents the threshold of the cones, the second that of the rods. Yet a consideration of the effective light stimulus Q shows that the two portions of the curve are not strictly comparable, because both N and p are different for rods and cones, respectively. The intensity I can provide a measure of the effective stimulus Q only when N and p are constant. The fact that p can change with time even when N is constant[3,6,7] renders exclusively photo-chemical interpretations of dark-adaptation untenable. Indeed, for a test-field of 1° angular diameter a temporal change in p of 0·5 (cf. ref. 6) accounts for a full two log units of dark-adaptation.

The idea of the effective stimulus is readily applied to the experimental results plotted in Fig. 1. It is then seen that:

$$\log R_Q = \log \frac{Q_c}{Q_r} = \log R_I + (p_c - p_r) \log A + p_c \log N_c - p_r \log N_r \qquad (2)$$

where the suffixes r and c refer to rods and cones, respectively. The data for N_c and N_r (at eccentricities ranging from 0 to 20°) were obtained from Østerberg's[8] counts. Baumgardt[9] has determined the variation of p_c with A; these findings were confirmed and supplemented by Brindley[10]. Baumgardt also showed that, at an eccentricity of 15°, p_r is 1 for A less than 1·3°. As it was not permissible to assume that this would be true also at smaller eccentricities (and, in a relevant experiment, Wolf and Zigler[11] had altered retinal eccentricity while altering the size of the test field), additional measurements were made with a Crookes adaptometer. The region examined was 8° above the right fovea, where Wald[12] carried out his peripheral measurements. The observer, R. A. W., was dark-adapted for 35 min., without having previously been exposed to bright light. Five test-fields, ranging in angular diameter from 0·60° to 1·45°, were presented in a random manner in three different sessions. The stimulus, modified by an Ilford 624 (green) 'Bright Spectrum' filter, was exposed for 1/25 sec., and the threshold criterion was two 'seen' out of three exposures, presented in rapid succession. The results are shown in Fig. 2: the lines, reproduced from Baumgardt[9], are consistent with these results. It would appear that even with a 1° test-field, applied relatively closely to the fovea, rod summation is found to differ from that observed for cones. The values R_Q, calculated from equation 2, are shown as black squares in Fig. 1 and correspond to the values R_I plotted as white or small semi-white circles, from which they have been derived.

Two features are outstanding: first, R_Q is approximately independent of A, the size of the test-field, and secondly, it is of the order of unity. This suggests that, when allowance is made for regional differences in receptor density and for the different summating properties of the dark-adapted fovea and periphery, respectively, rod and cone thresholds are approximately equal. This is true even when they are measured with a test-field so large as to cover the whole of the rod-free area.

The above calculation has involved two simplifying assumptions, both of which tend to make the calculated values R_Q too large. The cone density N_c

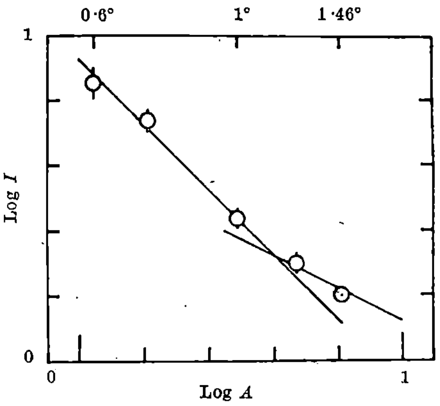

Fig. 2. Log threshold intensity (arbitrary units) as a function of the log test-field (arbitrary units). The angular diameters of the test-fields are shown at the top. Standard errors of the mean are indicated. The lines are reproduced from Baumgardt's data (ref. 9). For details see text

was taken to refer to all cones. If it is assumed tentatively that the number of 'green sensitive' cones forms only half to a third of the total, the log R_Q values corresponding to small values of A will be reduced by 0·3–0·5 and those referring to larger test-fields by not more than about 0·2. Again, the value of N_c was assumed to be constant throughout the rod-free area of the fovea. The removal of this assumption would reduce the log R_Q values for log A greater than 2·6 by less than 0·2. Owing to some uncertainty regarding the exact variation of foveal summation with area for very small areas, the R_Q values for larger test-fields are certainly the more reliable of the two. The additional corrections lead, therefore, to log R_Q values equal to, or less than, zero.

There is no need to labour the point, beyond stating that a single cone may well be as sensitive as a single rod, if not more so. It would be a bold man, indeed, who would introduce into the argument morphological differences between the two types of receptor. Cones are sometimes said to have special light-funnelling properties; human foveal cones, however, have a more rod-like appearance than the rods themselves, and one can scarcely even speculate on funnelling in a vessel the dimensions of which are comparable with the wave-length of light, and the optical properties of which are virtually unknown.

The analysis shown in Fig. 1 contains all the relevant results known to me with but three exceptions: first, Riezler, Esper and Meurers's[13], who failed to immobilize the observers' heads to an extent which is generally considered a minimum requirement (cf. also ref. 14); secondly, Craik and Vernon's[3], whose R_I value is shown in Fig. 1, but who do not seem to have specified the retinal eccentricity at which the rod portion of their results was obtained; and thirdly, Pirenne's[15], which raise a point of great interest. Using a blue test-field at 10′ angular diameter, he measured the absolute threshold in the fovea and at various eccentric locations up to 4°. Now Brindley[10] has shown that p_c equals 1 for blue test-fields as large as 13′ in diameter, whereas p_c equals 0·5 for smaller test-fields, red or green in colour. Clearly, an attempt to express a foveal threshold measured with a blue 10′-field in terms of the maximal foveal sensitivity (yellow-green) leads to an inadmissible situation, analogous to the one illustrated earlier by reference to the dark-adaption curve. As the relative number of 'blue' receptors in the fovea cannot be even guessed at, the only point which need be made is that Pirenne's observed value log $R_I \approx 2\cdot1$ reduces approximately to 1·1 when the corrections, previously mentioned, are applied. R_Q cannot be estimated.

A Photo-chemical Correlate

The approximate equality of rod and cone thresholds raises the question of the relative visual pigment concentrations in these receptors. Although there is no *a priori* reason why there should be direct proportionality between threshold and light-absorption (evidence is accumulating that such a relation need not obtain), one would not expect the concentrations to be greatly different. The first piece of photo-chemical evidence regarding this point comes from *in vivo* bleaching measurements on the squirrel's pure-cone retina[16]; it shows that the visual pigment density changes on bleaching by an amount commensurate with that found in experiments carried out on rod-retinæ. Brindley's sensory experiments[17] lead to the same conclusion.

Night Flying

The fact that, at small visual test-angles, the fovea and the periphery are approximately equally sensitive may have a practical sequel. At present, Service personnel due for nocturnal look-out or flying duties are kept in a state of near dark or red adaptation. In so far as the visual demands are only the detection of point sources of light, the sensitivity factor of not more than 5 or 6 which prolonged dark-adaptation bestows would scarcely seem to be worth the price possibly paid for it in terms of reduced morale. If the visual task involves the detection of 'dark shapes on the horizon', prolonged dark-adaptation is unavoidable. But when the object is the detection of point sources, dark-adaptation of a few minutes may well be adequate. Stars appear, after all, little brighter after 50 min. than after 5 min. spent in the dark.

Note added in proof. Since this paper was submitted for publication, Pinegin[18] has shown that, for very small test-fields, rod and cone thresholds are comparable in magnitude.

OBITUARIES

Dr. O. G. S. Crawford, C.B.E., F.B.A.

O. G. S. CRAWFORD, who died on November 28, 1957, was one of the best-known British archæologists of his generation. Born in India in 1886, educated at Marlborough and Keble College, Oxford, where he turned from classics to geography, he soon began to make original contributions to archæology. He was impressed with the importance of studying the environment of early man, and the influence of geographical factors upon human affairs, ideas which found expression in his first book, "Man and his Past" (1921). His interests led him to undertake an archæological survey of an area near his home, which was published in 1922 as "The Andover District", and is still well worth reading. In 1913 he joined the Wellcome expedition to the Sudan, but this opportunity was cut short by the outbreak of the First World War. After a period in the infantry, he joined the Royal Flying Corps as an observer, being shot down and taken prisoner in 1918. There were few at that time who foresaw the special contributions that aerial survey could make to archæological studies, but Crawford's field-work on the chalk downs had shown him the use of shadows in studying complicated earthworks, and his war-time flying experience impressed upon him the value of the aerial view for the understanding of archæological sites.

At the time of the First World War archæological posts were few and offered little prospect of a career, but Crawford's appointment in 1920, as the first archæology officer at the Ordnance Survey, provided just the opening he needed. Until the time of his appointment, the archæological information embodied in Ordnance maps was largely in the hands of the field staff, who might have little knowledge of archæology, no matter how competent they were at surveying. The task confronting Crawford was immense; however, he found time not only for routine revision of archæological detail on the Ordnance maps, but also for the preparation of a series of 'period' maps, of which that of Roman Britain was the first and best known. The value of this work at the Ordnance Survey, undertaken with a minimum of assistance, may be seen in the official large-scale maps of the United Kingdom, which attain a standard in archæological cartography scarcely approached elsewhere. The results of Crawford's field surveys were published as individual papers or larger works, such as "The Long Barrows of the Cotswolds" (1925), an important account of a selected class of monuments.

It is probably as the pioneer of archæological air photography and as the founder-editor of the quarterly journal *Antiquity* that Crawford will best be remembered. His achievement in the first sphere culminated in the publication, with Alexander Keiller, of "Wessex from the Air" (1928), a splendidly illustrated account of an archæological air reconnaissance of Salisbury Plain and adjacent areas, which sets a new standard in archæological research. In 1928, Crawford visited the Middle East, in an attempt to secure the preservation of air photographs taken by the Royal Air Force, and to direct attention to the unique possibilities open to air photography for research in that region. He was ever keen to foster the development of the subject in Britain, either publishing discoveries himself or making known the work of others in the same field. Much of his later work appeared in *Antiquity*, over which he took great pains, making several special journeys to Europe and North Africa. If the first dozen years of that journal represent its best period, it has always provided a forum for review and criticism and for exchange of ideas on all branches of archæology.

As an archæologist Crawford had a flair for field survey, which served him well when studying earthworks, either on the ground or from the air. He was a marked individualist, gifted with considerable powers of expression, to which the pages of *Antiquity* bear witness. For such a person, relations in an official department cannot always have been easy, but he had a great capacity for friendship, and was able to awake in others something of his own immense enthusiasm for his chosen subject. He was created C.B.E. in 1950, elected Fellow of the British Academy in 1949 and awarded honorary degrees by the Universities of Cambridge and Southampton.

J. K. S. St. Joseph

Prof. W. J. Jongmans

The sudden death of Prof. Jongmans, at Heerlen on October 13, robs the world of one of its most active palæobotanists. Willem Josephus Jongmans was born on August 13, 1878, at Leyden, where he received his early education. A student of the University of Leyden and later of the University of Munich, he was awarded a D.Phil. of the latter University in 1906. In the same year he was charged with palæobotanical research in one of the Dutch Government Services concerned with fuel resources, and the following year, 1907, was appointed a curator at the Rijksherbarium in Leyden. In 1919 he was released from the post at the Herbarium to become head of one of the departments in the Government Geological Service. While holding this position Jongmans was nominated head of the office at Heerlen, which led directly to his appointment as director of the Geological Bureau of the Netherlands Mining District at Heerlen, a post which he held from 1924 until his retirement in 1946. In addition to being director of the Bureau he was, from 1932 onwards, extraordinary professor of palæophytology in the University of Groningen.

Throughout his career, Jongmans's interest was directed towards the study of the flora of the Carboniferous period, and his extensive knowledge led to the publication of many authoritative papers on the plants from such widely distant places as Limburg and Sumatra, North America and Anatolia, Peru and Egypt, Spain and the U.S.S.R. But perhaps he is best remembered in Britain for the excellent "Monograph of the Calamites of Western Europe", written in collaboration with Kidston (1915–17), and the monumental "Fossilium Catalogus", published in twenty-two parts between 1913 and 1937. Jongmans's interest was not, however, confined purely to the plants, but extended over the floral assemblages of which they had been members. Early in his life he made a specialist study of the stratigraphic relations of the Carboniferous floras and he was responsible for many publications on this aspect of palæobotany. We should remember also his very important opinions on the nomenclature of fossil plants.

Though he officially retired in 1946, Jongmans carried on active research until the very last, and he was often to be seen in the Geological Bureau, which was only a short distance from his home at Heerlen. Time was always found to welcome and encourage a visiting palæobotanist who had come to see the magnificent collections and discuss problems with the master who had done so much for the furtherance of his subject. In recognition of his services to his country and science, Jongmans had been elected an Officer in the Order of Orange-Nassau and a Knight of the Order of the Netherlands Lion.

Alan Wesley

Mr. C. T. Gimingham, O.B.E.

Through the death of Conrad Theodore Gimingham on November 16, agricultural entomologists and plant pathologists have lost one of their pioneers and dearest friends.

Gimingham joined the staff of the Ministry of Agriculture's Plant Pathology Laboratory at Harpenden, as entomologist in 1928, at a most important time in the development of agricultural entomology. The specialist biological advisory services in agriculture had started some years earlier when several young and enthusiastic biologists were stationed at universities and agricultural colleges to investigate local problems and give advice to farmers. The Plant Pathology Laboratory acted as their co-ordinating link, and Gimingham came into very close touch with all the advisory entomologists. In 1944 he succeeded the late Sir John Fryer as director of the Laboratory and as chairman of the Conference of Advisory Entomologists, with which he had been closely associated since his appointment. It was one of his great delights, and although he relinquished his chairmanship shortly after his retirement, he remained a member until his death. The modern developments in the insecticide field, with which Gimingham had much to do, started in the 1920's, and he proved to be an ideal person to guide the biologists who had become available, to see that the best use was made of the new materials provided by research and industry.

In the late 1930's it became evident that there was a real need to institute some form of approval scheme for crop-protection chemicals. It was largely through Gimingham's ability for painstaking negotiation and the deep respect in which he was held by both sides that in 1942 the Ministry and the Association of British Insecticide Manufacturers instituted the voluntary Crop Protection Products Approval Scheme. The success of this venture bears testimony to his achievement.

He was deeply occupied in phytosanitary work at home and in Europe, for example, with the Colorado beetle, and he must be given a good deal of the credit for preventing this pest from becoming established in Great Britain after the Second World War.

Perhaps Gimingham's greatest influence lay in his keen interest in the development of the younger entomologists. His quiet modesty, kindliness and sincerity made him the ideal guide, philosopher and friend. We were happy and privileged to place our trust in him, and many of us are thankful for his help.

Gimingham was closely associated with the Royal Entomological Society and the Association of Applied Biologists, of which he was president during 1938–40.

He married, in 1912, Muriel Blake, who survives him together with two sons and a daughter.

F. H. Jacob

NEWS and VIEWS

Rothamsted Experimental Station : Sir William Ogg

The retirement of Sir William G. Ogg from the directorship of the Rothamsted Experimental Station is announced to take place next September. He succeeded Sir John Russell in 1943, having previously been director of the Macaulay Institute for Soil Research, near Aberdeen. At Rothamsted he continued the expansion begun in the inter-war period, and successfully organized the inclusion of the Soil Survey of England and Wales previously directed by the late Prof. G. W. Robinson, of Bangor, bringing Dr. A. Muir from Aberdeen as the new head. As the owner and manager of a well-known farm in Aberdeenshire, Sir William has had exceptional opportunities of appreciating the new, and often difficult, agricultural problems of the post-war period and the ways in which modern science could contribute to their solution. His genial approachability has given him considerable popularity in agricultural circles, and on a variety of occasions he has been asked to undertake official visits overseas to advise on problems where his knowledge and shrewd judgment proved very helpful. His friendly relations with the Rothamsted staff enabled the expansion of the various departments to proceed smoothly, and when the Station finally obtained vacant possession of the attractive old manor house, which had been acquired with the estate in 1934, he had it converted into a hostel, thereby providing living quarters for some of the staff, as well as additional accommodation for conferences and other gatherings. His useful term as president of the Society of Chemical Industry will long be remembered. It is understood that he will retire to his farm, where all his friends and former colleagues will wish him and Lady Ogg many happy years of useful activity.

Mr. F. C. Bawden, F.R.S.

Mr. F. C. Bawden, head of the Plant Pathology Department of the Rothamsted Experimental Station, has been appointed director of the Station in succession to Sir William Ogg. Mr. Bawden, who is forty-nine, is well known for his brilliant researches on the virus diseases of plants, for which he was elected a Fellow of the Royal Society in 1949. His appointment shows the growing importance of plant pathology in Great Britain: the directorship has hitherto been from the side of soil and plant nutrition, the original, and for long the main, subject of the Rothamsted investigations. After a distinguished career at Cambridge, he went to Rothamsted in 1936 as physiologist to the Virus Disease Unit and soon attracted attention by identifying, in conjunction with his biochemical colleague, N. W. Pirie, a number of plant viruses and virus strains as nucleoproteins. They isolated in crystalline form the tomato bushy stunt virus, the first ever to be so obtained. With another colleague, A. Kleczkowski, much valuable work has been done on the serology of the viruses. New methods have been discovered of inactivating viruses without destroying their antigenicity. Mr. Bawden has also organized much valuable field work to discover the factors affecting the rate of spread of virus diseases, in the hope of finding measures of control. He has shown that he not only possesses high scientific ability and power of organization, but also that he can appreciate scientific merit in others. Under his direction, Rothamsted may confidently be expected to maintain the high position it has hitherto held among the world's institutes for the development of agricultural science.

Ministry of Agriculture, Fisheries and Food ; Fishery Research : Mr. G. M. Graham, C.M.G., O.B.E.

The Ministry of Agriculture, Fisheries and Food has announced the retirement on February 21 of Mr. G. M. Graham, director of Fishery Research. Mr. Graham has served on the Ministry's staff for thirty-eight years, having joined the staff of the Lowestoft laboratory in 1920. In his earlier years, Mr. Graham was especially concerned with research on the cod, and his work laid the foundations for our knowledge of that species in the North Sea. In 1927 he was loaned to the Government of Kenya to survey the fisheries of Lake Victoria; and in 1931 he was loaned to the Biological Board of Canada to study the herring in Passamaquoddy Bay. He was Buckland professor for 1939. Mr. Graham served with the Royal Navy during the First World War, and during the Second World War he was with the Ministry of Aircraft Production in operational research and served with the honorary rank of wing commander in the European operations with the Royal Air Force. He was made O.B.E. (Mil.) in 1946.

On his appointment as director of fishery research in 1948, Mr. Graham turned himself enthusiastically to problems arising out of the War and to the development of modern fisheries investigation. He will be especially remembered for the encouragement and direction that he has given to the mathematical treatment of the study of fish populations. During his directorship the fisheries research staff has increased greatly in size, and the number of research ships was increased to include the *Ernest Holt*, which has carried the English investigations far into the north-east Arctic. A new laboratory for shell-fish investigations was also started at Burnham-on-Crouch under the leadership of Dr. H. A. Cole. In 1954 Mr. Graham was made C.M.G.

Mr. R. S. Wimpenny, O.B.E.

Mr. R. S. Wimpenny, who has been deputy director of fishery research at Lowestoft since 1948, has been appointed director of fishery research in succession to Mr. Graham. Mr. Wimpenny joined the staff at the Lowestoft laboratory in 1925 and was chiefly engaged on plankton research, in which he advanced our knowledge of the fat content of copepods, and the biology of diatoms. In 1927 he left the Ministry's staff to become director of fishery research to the Egyptian Government. While in Egypt he established a successful fishery for grey mullet in Lake Quaroun, the mullet fry being transported by air 100 miles inland from the sea. Mr. Wimpenny rejoined the Lowestoft staff in 1932 and resumed work on plankton. He has also done research on the plaice, which was the subject of his lectures as Buckland professor in 1949.

During the First World War Mr. Wimpenny served as a pilot in the Royal Flying Corps and, later, in the Royal Air Force. During the Second World War he was district inspector of fisheries for the eastern part of the south-east district of England and was Port Fishery Captain of Rye. Since the War he has been especially responsible for leading the work of the Lowestoft laboratory in research in the near fishing waters. He has also given much time to the work of the International Council for the Exploration of the Sea, and has been chairman of its Consultative Committee since 1951. Mr. Wimpenny was made O.B.E. in 1957.

Geological Society: Awards for 1958

The Council of the Geological Society of London has made the following awards for 1958: *Wollaston Medal:* to Prof. Pentti Eskola, doyen of Finnish geologists, distinguished for his contributions to metamorphic geology, especially in regard to the redistribution of material during metamorphism, the origin of granitic magmas and the conditions during the earliest geological time; *Murchison Medal:* to Dr. R. G. S. Hudson, for outstanding researches on the Carboniferous rocks of the north of England, in particular on their stratigraphy and palæontology; in recent years his work has been connected with the search for oil in the Middle East; *Lyell Medal:* to Dr. Helen Muir-Wood for her fundamental contributions to knowledge of the Brachiopoda; *Wollaston Fund:* jointly to Mr. R. J. A. Eckford for his work on the Geological Survey in connexion with the igneous rocks of Scotland and in particular his investigations of the geology of the Southern Uplands, and to Mr. W. Manson for his work on the Geological Survey in connexion with the stratigraphy and palæontology of the Scottish Carboniferous rocks; *Murchison Fund:* to Dr. Geoffrey Bond in recognition of his researches into the Carboniferous stratigraphy and palæontology of Britain, and the Karroo system and later deposits of southern Africa; a moiety of the *Lyell Fund* to Mr. H. R. Warman for his stratigraphic and tectonic work in Sicily and South Iran, and his contribution to oil and gas exploration in the United Kingdom; another moiety of the *Lyell Fund* to Dr. Eileen Lind-Hendriks, in recognition of her researches on the geology of the Cornish peninsula.

Extension of Imperial Chemical Industries' Research Fellowship Scheme

Important changes have been made in the scheme of post-doctorate fellowships for research in chemistry, physics, engineering and related sciences offered by Imperial Chemical Industries, Ltd. Since the start of the scheme in 1944, Imperial Chemical Industries Fellowships have been tenable in a considerable number of British universities, but not in all. In future, the scheme will apply to all universities in the United Kingdom, to the University College of North Staffordshire and to Trinity College and University College, Dublin. The number of fellowships will be increased from 92 to 103. Individual fellowships will now range in value between £700 and £1,000 per annum, and the scheme is guaranteed for five years. As in the past, the universities and colleges will themselves make the appointments and draw up the regulations governing the holding of the fellowships. Imperial Chemical Industries exercises no control over the conduct of the research work. It is hoped that the scheme will help in promoting vigorous schools of research in British universities, and so contribute to the advancement of scientific knowledge upon which industrial progress ultimately depends. The enlarged scheme will cost approximately £93,000 per annum—a sum which, when added to other financial assistance given by Imperial Chemical Industries to universities and learned societies, raises the Company's total contribution to scientific education and research in Great Britain to more than £300,000 per annum.

Team-work and Discovery in Science

In his Perkin Medal Address, entitled "The Metallurgy of the Unusual", delivered before the American Section of the Society of Chemical Industry in New York on January 10, Dr. W. S. Kroll took issue with those who claim that 'the days of 'sealing wax–baling wire' science are over.' The fight of the individual against the collectivity in which he lives is as old as humanity and it will never cease to exist. While Dr. Kroll granted that the team could not be avoided in development work, he challenged its justification in research. He questioned whether leadership can be created in such a system: when teams are put to work to make important discoveries or inventions, they either fail dismally or are far too costly. He maintained that many laboratories in the United States are over-fond of gadgets and complicated equipment which often take more time to repair than to use. These instruments remove the investigator from his experiment; automatic research tools can thus be a great handicap to invention and progress. We have to offer the recalcitrant lone-wolf research worker some asylum since he is now menaced with extinction. His help is indispensable in the early stages of any new development and he acts like a scout, prospecting new territory before it is exploited by the crowd. The inventor or scientist needs self-expression and the affirmation of his personality: to try to depersonalize him in a team is psychologically a great mistake. Very great discoveries, in Dr. Kroll's opinion, are still so close to the surface that they can be unearthed with little expense by nonconformists with an inquisitive mind, with knowledge, the urge to create and who are prepared to accept sacrifice as a way of life.

Acta Meteorologica Sinica

THREE issues of the periodical *Acta Meteorologica Sinica* have been received from the Institute of Geophysics and Meteorology of the Academia Sinica, Peking. Each contains six or seven papers. The papers themselves are in Chinese but each has a summary in either English or Russian, with roughly equal numbers of summaries in each of these languages. In the issues received, all the papers are on dynamical and synoptic meteorology with the exception of one on hygrometry. Frequent references are made to recent European and North American meteorological literature. Typical titles are "A Test for 24 and 48 hr. Numerical Forecasting with a Quasi-geostrophic Two-parameter Model" and "Statistical Investigation on the Blocking Situations over Asia". It does not seem that numerical forecasting with electronic computers is yet under examination in China, but Fjørtoft's graphical method is in use. Study of the papers would be easier if titles in English or Russian were given to figures and tables and perhaps even isopleths might be labelled, and columns and rows headed in one or other of those languages. It would also be very helpful if personal names of authors could be given in Latin script as well as in the Cyrillic form.

Cleveland Museum of Natural History, Ohio

UNDER the title of "A Reason for Pride" (Cleveland, Ohio: Cleveland Museum of Natural History, 1957) an attractive booklet describes how the site of the well-known Cleveland Museum of Natural History is required for a development plan of the city and the progress that the Trustees have made with a new building. At the outset, mention is made of the great assets of this Museum, and a brief résumé is given of the chief collections assembled during the past thirty-seven years. The new site is in Wade Park and covers eleven acres. Building is already in progress, and when completed will include a Hall of Nature, a Gallery of Man, a Hall of Science, and a Planetarium. In addition, the grounds surrounding the Museum will be made into a Nature garden containing outdoor exhibits of flowers, shrubs and trees native to the Cleveland district. All exhibits, both inside and out, will be planned in sequence to cover systematically the subjects of Nature and science in all their phases.

Agricultural Research

"FUNDS for Research in Agricultural Experiment Stations, 1953–54" is No. 8 in the series "Reviews of Data on Research and Development" issued by the U.S. National Science Foundation. Expenditures for research by agricultural experiment stations in the United States increased tenfold from 7 million dollars in 1920 to more than 74 million in 1953–54; 17 million for basic research and 57 million for applied research. Research funds for these stations came, for the most part, from the State governments and supplemented the core of support provided by the Federal Government. The States accounted for 45 million dollars; the Federal Government for 13·5 million, and other sources, such as sales and royalties, for 16 million. The 53 stations, practically all administered by the land-grant colleges and universities, are the fountainhead of agricultural research in the United States. The largest amounts were devoted to animal production and field crops; the smallest, to genetics and farm forestry. Copies of the report can be obtained from the National Science Foundation, Washington 25, D.C.

Tetrahydrothiophen

TETRAHYDROTHIOPHEN (called tetrahydrothiophene in the trade) is a colourless liquid with a fairly high boiling-point (above 120°) but low flashpoint (64° F.) which is now in production in England by Robinson Bros. Ltd., Ryders Green, West Bromwich. The substance has a strong odour of coal-gas and is used in odorizing colliery methane and natural gas (see *Nature*, **180**, 1444; 1957) and also re-formed petroleum gases before they are used in town gas supplies. These gases are otherwise practically odourless and in that condition would not betray their presence in case of leakage. The odorized gases, on the contrary, have the characteristic smell of ordinary coal-gas. Details are available from the manufacturers on request.

Shelter Belts and Microclimate

A LINE of work in the Forest Products Laboratory with a probable future for research is connected with shelter belts. In the past century, in the south of Scotland and the north of England, shelter belts were planted by landowners for the protection of stock and crops. In order to save land, they were usually much too narrow and often consisted of Norway spruce. When the trees had attained a certain height and weight in the crowns a winter gale would either blow them down or more usually make a hole at one end from which successive gales would sweep away the plantation. The Forestry Commission has recently published its Bulletin No. 29 on "Shelter Belts and Microclimate" (London and Edinburgh: H.M. Stationery Office, 1957), by Dr. J. M. Caborn, of the Department of Forestry, University of Edinburgh, to whom it gave a grant and assistance in carrying out the research work. The investigation included wind, temperature, atmospheric humidity, evaporation and transpiration, soil moisture, precipitation and snow distribution, the economic significance of the influences of shelter belts and general conclusions on shelter-belt types, lay-out and structure. Help was received from the Department of Meteorology, Imperial College of Science and Technology, London, from the Danish Heath Society, from the Swiss Forest Research Institute, Zurich, from the Meteorological Office and from colleagues on the forestry staff at Edinburgh. The results, if put into force, should provide a different type of shelter belt in Britain both in density and quality of timber. The Bulletin should prove of use in Colonial countries where shelter belts on a larger scale are very much needed for the improvement of agricultural crops and stock.

Biochemistry and the International Union of Biological Sciences

A COMMITTEE of the Section of Biochemistry of the International Union of Biological Sciences has recently been formed. It is essentially a co-ordinating committee between the International Union of Biological Sciences and the International Union of Biochemistry. It is assumed that this committee will be specifically concerned with chemical biology within the framework of the Unions federated in the Council of Scientific Unions. An important function of the committee will be to make proposals for international symposia to both Unions. It is hoped that a full committee meeting will shortly be held, perhaps during the fourth International Congress of Biochemistry in Vienna in September 1958. The committee as at present constituted consists of M. Florkin (Liège, *president*), O. Lindberg (Stockholm), R. Brunel (Toulouse), F. Lynen (Munich), P. Boyer (Minneapolis) and T. W. Goodwin (Department of Biochemistry, University of Liverpool, *secretary*).

Conference on Salt Marshes

THE Marine Institute of the University of Georgia has organized a Conference on Salt Marshes, to be held at Sapelo Island during March 25–28, 1958. The Conference is being sponsored jointly by the National Science Foundation and the Marine Institute. It will be international in character. Its purpose is to bring together scientists who are working on, or interested in, salt marshes, for discussion of research on this particular environment. An invited group of about twenty-five people will participate in the Conference; invitations will be extended on request to a limited additional number of persons who wish to attend at their own expense. The Conference is under the direction of Dr. Alfred C. Redfield, of Woods Hole, Massachusetts. Further information can be obtained from Dr. Robert A. Ragotzkie, University of Georgia Marine Institute, Sapelo Island, Georgia.

Low-Temperature Physics Conferences

THE sixth international conference on low-temperature physics will be held in Leyden during June 23–28, 1958, in connexion with the fiftieth anniversary of the first liquefaction of helium by Kamerlingh Onnes. Further information can be obtained from Dr. J. van den Handel, Kamerlingh Onnes Laboratory, Leyden, The Netherlands. A conference of the First Commission of the International Institute of Refrigeration will be held in Delft during June 17–20, 1958. At this meeting technical aspects of low temperatures will be discussed as well as scientific subjects. The secretary of the Delft conference is Prof. B. S. Blaisse, Mijnbouwplein 11, Delft, The Netherlands.

Announcements

MR. R. F. HAYMAN, industrial gas officer of the Gas Council, has been appointed chairman of the Industrial Gas Development Committee of the Council in succession to Mr. W. H. Tarn, whose term of office as chairman of the Committee expired on December 31.

DR. H. O. J. COLLIER has been appointed director of pharmacological research at Parke, Davis and Co., Ltd., Hounslow, Middlesex, from February 1. For the past twelve years, Dr. Collier has been head of the pharmacology department at Allen and Hanburys, Ltd., Ware, Herts.

RECOMMENDATIONS for the Meldola Medal, which will be awarded to the chemist who, being a British subject and less than thirty years of age on December 31, 1957, shows the most promise, as indicated by his or her published chemical work; and for Beilby Memorial Awards, given to young British investigators in science to mark appreciation of records of distinguished work, should be made by February 28. Further information can be obtained from the Royal Institute of Chemistry, 30 Russell Square, London, W.C.1.

THE Society of Protozoologists is to publish "A Catalog of Laboratory Strains of Free-living and Parasitic Protozoa", with sources from which they may be obtained and directions for their maintenance. This will appear as an integral part of the February issue of the *Journal of Protozoology* (5, No. 1). Reprints, which will be sold at a nominal cost, can be ordered from Dr. D. M. Lilly, Society of Protozoologists, St. John's University, Department of Biology, Jamaica 32, New York.

May and Baker, Ltd., state that from time to time they still receive empty Winchester quart bottles containing small amounts of sodium wire. Although all bottles that have been used for ether are examined before washing, it is difficult to detect such small pieces of sodium. This practice has resulted in several incidents, potentially serious, in the bottle-washing plant. In the interests of safety, any residual sodium metal used to dry the ether should be carefully and completely decomposed with a low-boiling alcohol before return to the supplier. Drying in this way is not necessary with the very dry grade of ether now available when required.

THE tenth British Mathematical Colloquium will be held in Reading during March 26–28. Further information can be obtained from J. E. Reeve, Department of Mathematics, The University, Reading.

THE Anniversary Meeting of the Chemical Society will be held in Bristol during March 31–April 2. There will be symposia on "Developments in Aromatic Chemistry", "Applications of Electron and Nuclear Resonance in Chemistry" and "Recent Work on the Inorganic Chemistry of Sulphur". Further information can be obtained from the Secretary, The Chemical Society, Burlington House, London, W.1.

IN *Nature* of December 28, 1957, p. 1448, reference was made in the article entitled "Lubrication and Wear" to an international discussion on the subject twenty years ago under the chairmanship of "the late Dr. H. J. Gough". We are glad to learn that a mistake was made and that Dr. Gough is still alive.

A WAGES POLICY

THE most pressing problem in the British economy is the race between the growth of personal incomes and the rise in industrial output. It was fitting, therefore, that, during the annual conference of the Institute of Personnel Management which was held at Harrogate during October 4–6, the 800 members attending were invited by Sir Richard Snedden, director of the Shipping Federation and chairman of the Industrial Relations Standing Committee of the British Employers' Confederation, to consider the means of dealing with this apparently intractable problem. Sir Richard made it very clear that there was no universal prescription for good industrial relations. These depended upon individuals; they had to be established gradually, patiently and even laboriously. The first essential is that each side must be confident of the good faith and integrity of the other. The next is leadership, but it must be responsible leadership including courage on both sides to take the unpopular decisions that responsibility sometimes entailed. The best way to build up confidence and to create effective leadership was for employers' and employees' representatives to meet frequently, preferably to discuss less-controversial matters, rather than meeting only at long intervals over such questions as hours of work and wages. The third essential is to avoid bringing in third parties except as a very last resort.

The classic approach to wages is that each industry should give the best wages that it could afford in order to get the best labour. The determining factor in wages-levels is the ability to pay, but there is no simple universal formula linking wages to production. There are seven reasons which seemed to make the discovery of a uniform magical slide-rule rather improbable.

First, it would be necessary for the Trades Union Congress and the British Employers' Confederation to reach an agreement and to bind their members. The Trades Union Congress is a powerful body, but it has never claimed to supervise, much less regulate, the wage claims of its component parts. The British Employers' Confederation is in the same position.

Secondly, the measuring rod usually suggested is the general index of industrial production. That index is not and cannot be comprehensive, and, at the outside, covers only half the employed population.

Thirdly, there are inherent weaknesses in any index of production. The proportion of products which are capable of unambiguous measurement and comparison at different dates is relatively small.

Fourthly, even if one took not the general index, but the component indices for individual industries or groups, labour is not the only claimant—although a most important one—to a share in the benefits of increased production. The consumer has a claim for lower prices. Capital also has a claim.

Fifthly, the actual increase in production would inevitably vary from industry to industry, from firm to firm, from department to department and even with individuals. It would not be easy to convince those acquainted only with their own personal increased efforts to share the benefits with others.

Sixthly, in considering wages, what are called 'fringe' benefits must not be left out of account. Reduced hours, increased pensions, and increased holidays can be just as inflationary as a direct increase in wages. They may even be more inflationary because they are likely to be more permanent.

Lastly, a scarcity of anything leads to higher prices and even a 'black market'. Why should labour be any exception ?

It is shortage of labour which makes employers yield increases of wages against their better judgment, and it might even be that shortage of labour sometimes compels some trades union leaders to put forward wage claims which they are not really convinced are in the best long-term interests of their own members.

The formidable difficulties are not all equally applicable to all industries. The course which Sir Richard thought must be pursued is first to create a climate of public opinion favourable to effective action to ensure that wage increases operate only where they are earned. The actual solution must be worked out by industries for themselves and to suit their individual circumstances.

The way in which wages policies in industry have developed was examined by Prof. D. T. Jack, of King's College, Newcastle on Tyne, chairman of the Courts of Inquiry into the engineering and shipbuilding disputes in 1957.

The traditional system of wage negotiation has some advantages. It provides a certain flexibility in the whole structure of wages. It has fostered a sense of responsibility on the part of the two negotiating parties in each trade and industry affected by this process.

There is, however, a frequently voiced demand for a strong type of unified, compactly designed or consciously planned wages policy to replace the traditional policy which has operated for so long. There are three main sources for this desire. The first is the recognition in many quarters that, in a period of inflation, the wage-price spiral is frustrating to all wage earners and most injurious to some.

The second is bound up with the effect of full, or, sometimes, over-full employment. Here we have a situation in which bargaining strength is heavily weighted on the side of the unions. Provided the monetary system is accommodating, it would be very surprising if wages were not pushed up by more than the overall increase in the productivity of labour, with the consequent increase in labour costs.

Then there are the economic planners, some of whom recognize that their calculations and guesses may be reduced to nothing if the wages section of the economy is allowed to follow its own course while the remainder of the economy is tied to a rigid plan.

If a unified wages policy is held to be desirable, the means of promoting it must be considered. Experience in other countries has not been encouraging. There have been experiments in the United States of America and certain countries of Western Europe which have not been strikingly successful in preventing inflationary tendencies. In Britain the trades unions have a strong dislike of any radical departure from the traditional sectional wage-bargaining procedure. Despite this, there has been some evidence in recent years that wage claims, apparently put forward independently, tend to conform to a certain pattern. Some years ago, nearly every wage claim was expressed in terms of an application for x shillings a week increase. The following year, nearly every wage claim was formulated in terms of an application for a percentage increase of y, and the following year it took a different form. The energy which might conceivably be devoted to the working out of a wages policy between, say, the Trades Union Congress and the British Employers Confederation, was concentrated on the type of suitable tactical procedures. In the old days, the usual practice was for wage claims to be presented, in the first instance at least, to the most prosperous industries. In recent years, there is some evidence that a rather different procedure has been followed. Wage claims have been presented, not to the most prosperous industries, but to other industries which, for some reason or other, are regarded as of public importance and which are either not profitable at all or barely profitable. Having succeeded there, the next step is to present a greater demand upon the prosperous industries with the simple argument that, if the non-prosperous industry can afford a wage increase of x shillings, then the more prosperous industries must obviously be able to afford x plus A shillings.

Some people believe that a wages policy could only be formulated by means of national negotiation at the very highest level. Representatives of the Trades Union Council would meet representatives of the British Employers' Confederation, and, between them, they would hammer out any wage increases for the following year. Such an experiment would meet with no success.

A wages policy cannot be considered in a vacuum, and must be related to the larger issues of economic, financial and monetary policy.

In the whole of the post-war period, successive Governments in Britain have failed to deal with those inflationary forces which lie within their own orbit of control; this complicates the question of what function any body charged with the formulation of a wages policy could usefully perform. Full employment with inflation requires the co-operation of the main economic groups within the community. How can that co-operation be most effectively secured ?

Do the existing procedures for arbitration in Britain encourage inflationary tendencies ? There would be considerable danger if any arbitrator were to obtrude into his decision his own personal judgment of the wider consequences of his award, if the wider consequences were not dealt with in evidence before him by people who were competent to present that evidence. If one or other of the parties appearing before an arbitrator were to present a statement on the wider issues for the economy as a whole, he would probably be told by the other party that it was a matter not within his competence.

The suggestion that arbitration should be made compulsory does not make for a more satisfactory solution. That being so, does the court of inquiry procedure provide a more elastic means of coping with the problem than the arbitration procedure ? To some extent it does, because the terms of reference of most courts of inquiry enable these courts to inquire into the causes and circumstances of the dispute. There is the further point that the reports of courts of inquiry are generally reasoned statements and not merely decisions, as in the case of awards of arbitration.

On the other hand, reports of courts of inquiry do not provide a complete answer because their terms of reference again generally limit inquiries to the particular dispute which has arisen between the parties, and it is not usual for these courts to seek evidence on the wider issues which may be involved in a particular claim.

One of the main gaps in the present system of industrial relations in Britain is that, in the past, there has been no body which would speak with authority on the wider issues which are raised by major wage claims on the economy as a whole. Now, however, there is the Council on Prices, Productivity and Incomes. What good can such a body do ? Parties to a dispute represent sectional interests, and their submissions are very properly dominated by those sectional interests. If we cannot go to the parties for enlightenment, where can we go ? One cannot look to Government because of the persistent record of Government failure to deal with those inflationary forces which lie within the power of the Government to control. Governments which have failed in their responsibility are scarcely entitled to admonish or exhort the public, or sections of the public, for their apparent misdeeds. Moreover, a Government which intervenes in industrial disputes in a manner which is intended to influence a result could scarcely be said to be performing its traditional function of 'keeping the ring'. At the lower, administration-level, only two departments are concerned: the Treasury and the Ministry of Labour. Neither is quite fitted to perform the function which is now required. The Treasury is too far removed from the world of industrial relations and too academic in its approach to command the attention of the public or the interested parties by its bulletins or by its announcements. The Ministry of Labour probably has its ear too close to the ground and is too preoccupied with individual disputes to go far beyond its appropriate brief.

Those concerned with the conjoint problem of inflation and full employment must be prepared to do some fresh thinking about the traditional arrangements for dealing with wages generally. Up to the present, the record is mainly one of failure. Governments have failed, and the two sides of industry have equally failed, to show any imaginative approach to the issues which have now become real.

The attitude of the trades unionist to scientific development and human relations in industry was put by Lewis Wright, general secretary of the Amalgamated Weavers' Association and chairman of the Trades Union Congress Scientific Advisory Committee (see *Nature*, **180**, 1013 ; 1957). No trades union, said Mr. Wright, opposes the development of automation, but none will approve the development of the machine at the expense of human dignity. The trades unionist wishes to see the machine exploited and not the worker ; the latter should receive some of the benefits accruing from the exploitation of the machine.

Besides the plenary sessions, a series of sectional meetings was held to consider the role of the shop steward in industry, industrial conciliation and arbitration, education for management, job analysis for managers and other staff, and ergonomics and industrial management. Reports of all these meetings have been published in the *Journal of the Institute of Personnel Management* (34, No. 342 ; Dec. 1957).

THE HOME UNIVERSITIES CONFERENCE

THERE can be no doubt that the Home Universities Conference, held in mid-December each year, is achieving increasing importance. The topics chosen for discussion are always live, as the fact that the Conference is sponsored by the Committee of Vice-Chancellors and Principals should guarantee. In addition to four or so delegates from each university, there are always representative guests present—members of the University Grants Committee, of the Ministry of Education, headmasters and headmistresses of schools and distinguished visitors from Britain and abroad.

Last December, the first subject for discussion was "The Place of Residence in the University To-day"—chosen because of the recent publication of the report of the sub-committee of the University Grants Committee on halls of residence. The Conference was clearly a strong believer in the educational value of halls of residence, but doubted whether they are being provided quickly enough. "Every new generation is a new invasion of savages", and if it behoves universities to play their part in civilizing their students, halls of residence are demonstrably among the most efficient means for doing this. As Prof. W. R. Niblett said, they should not be merely fringe enterprises in a university: they are closely related to its very *raison d'être*. But though professors may almost all be converts to the cause of halls of residence, they are sometimes apt to regress rapidly when asked to make a contribution at a financial cost to the development of their own departments. Prof. Seaborne Davies penetratingly remarked that it is chiefly upon the support of the disinterested that halls of residence have to rely.

During the Conference someone might have pointed out that halls of residence are among the best assets to a modern university in capturing good students for any department. It is not in the quality of their research or their teaching that modern universities are most open to criticism. These often, indeed, are first-rate. But too many students who might in favourable circumstances have emerged as leaders, with a wide interest in life and able to make human contacts with ease, remain over-specialized and insufficiently awakened; and with increasing numbers of 'first generation' students in our universities this is increasingly true. Industry to-day realizes more and more that a period in a good hall of residence is an immense asset to a student, and especially perhaps to a scientist. For many scientists in their maturity are not going to be primarily scientists but managers—and therefore makers—of men.

The introductory speeches, and also the contributions to the discussion on halls of residence, acute though some of them were, scarcely brought out sufficiently fully the differences between the older and newer universities in the living conditions they provide. It was suggested, for example, that really large halls in modern universities might still have something of the same civilizing effect on their inhabitants as Trinity College, Cambridge—for few declared that to be too large. In actual fact, many do, of course, regard Trinity College as far too big; but it is at least doubtful whether a hall of residence in a modern university will be so potent in its influence unless size is limited to a reasonable number of students under each warden (possibly not more than one hundred), each student having a private room of his own in which to work and live a private life. Of course, this is not to deny for a moment, any more than the Niblett Report does, that groups of halls of residence on one site have many possibilities.

At the second session of the Conference, on "Procedure for the Selection of Undergraduate Students", the different points of view on this subject of people from universities and schools showed up sharply. Sir James Mountford, commenting on the report published a few months ago under the auspices of the Committee of Vice-Chancellors on "Applications for Admission to Universities", emphasized that the basic problem was the number of applications compared with the number of vacancies. In his view, there was deplorable chaos in the procedure for the selection of students. He did not believe that a clearing-house system was a practicable solution to the problem, though universities might well be less secretive about the number of vacancies they had. It seemed to him, however, that the chief remedies must be supplied by the schools themselves. They should refuse to let their weak candidates apply for university entrance at all. They should support a movement for transferring the parts of the examination for the General Certificate of Education on which selection is based, from July to some time in the spring term.

As representatives of the schools hinted, these proposals really left the universities with very little of the burden of the problem: it was evidently the schools, not the universities, who were required to make the difficult adaptations. It is not easy to refuse candidates a chance of getting into a university if parents and boys themselves are keen on such a chance being allowed. As for change of date for the General Certificate (Advanced Level) examinations: it must be remembered that sickness in schools is at its maximum in the spring term, and that the effect of such a change might be to cut to five terms the total sixth-form course of a number of boys and girls—both those hoping for a university career and those with no such intention—who needed at least six if they are to be given an adequate sixth-form training. In a sincere and practical address, Miss M. J. Bishop, herself a very experienced headmistress, protested against the continuing onerous weight of faculty requirements. These were a threat to all unexamined sixth-form work. The rampant individualism of universities was the despair of the schools.

Dr. C. L. Pratt, of Christ's College, Cambridge, supported the idea that a vigorous pruning of faculty requirements should be made. The Imperial Chemical Industries' bursary scheme suggested that some schoolboys at least can be orientated, after they have entered a university, to a scheme of specialized study—for example, in science—when their sixth-form course had been almost entirely concentrated on the arts. He emphasized that what matters most in choosing candidates rightly for university entry is the shape of the curve of the candidates' progress up to the time of selection: Was a particular boy or girl likely to develop a great deal, or was he already near his peak ? He suggested that the selector must not be professionally and whole-time on the job: he should be made to live with the people he chooses. Selectors should suffer the consequences of their own decisions.

In the discussions on this key subject of selection for university entrance, it is to be noted that the headmistresses were able to speak knowledgeably of the problems of entry to both older and newer universities. No headmaster from a grammar school made a contribution, and the heads of public schools who spoke could only speak about selection for Oxford and Cambridge. One fancies that within the next few years, with the intense pressure on university entry and little chance of any significant increase in the number of students taken at Oxford and Cambridge, the public schools will have to make themselves much more aware of conditions at modern universities. Incidentally, it was pointed out that in Scotland the examinations which determine entrance qualifications to universities start in mid-March each year. But England rarely learns from Scotland in such matters.

The final session of the Conference tackled the problem of academic mobility. The investigation undertaken by the Association of University Teachers in 1956 suggested that too many members of university staffs stayed too long in one place. 22 per cent even of professors have never taught in a university other than that in which they hold their chair. Prof. A. G. N. Flew, of the University College of North Staffordshire, pointed out that a period of university teaching overseas could be of immense value in broadening the mind—in indicating, for example, that the English division of the curriculum into arts and sciences was not part of an inevitable ordering of things. Dr. R. S. Aitken, vice-chancellor of the University of Birmingham, considered that mobility among science staff was about right but that among arts staff it was insufficient.

Discussion in the Conference indicated that there was a widespread feeling that at present there was too great a degree of academic immobility. In particular, it was held that universities ought to advertize senior lectureships wherever possible, whereas the almost universal present practice is to promote from within the institution. Strong pleas were entered for further exchanges within the Commonwealth: a number of Commonwealth countries are at a critical stage in their university development, and it would be of the greatest value to them that some of the best people should have a period of university service in them. But pleas were also entered for exchanges within the United Kingdom itself: even one term of teaching in a different university might be a great stimulus.

With the rapid increase in numbers of university staff during the past few years, there is to-day an altogether disproportionate number of university lecturers in the 30–40 age group. Some speakers saw a good deal of discontent ahead when many of these people were still lecturers and yet in the 50–60 age group. They suggested that this was an argument for providing more senior posts—more new universities even—for then there would be more chairs for which to compete.

There appear to be great differences between university departments of applied science in the closeness of their contacts with industry. In some, it is standard practice for lecturers in, say, engineering to be taken from industry and to return to industry after a period of teaching and research. In other universities this is rare. But the Conference did not clearly show what its mind was in this matter.

In fact, the Home Universities Conference is much better as an assembly to which thoughtful and challenging contributions can be made either from platform or floor than as a place in which there is a keen to-and-fro discussion. Perhaps this is inevitable when there is a large and representative collection of university dons assembled with their vice-chancellors in the comfortable and dignified—if apparently underground—William Beveridge Hall of the University of London. Be that as it may, British universities in general are in great debt to the University of London for its kindly and hospitable welcome to a Conference which is bringing together, as no other conference does, people from the staffs of all British universities at a time of year when they are prepared to be thoughtful in a creative way.

AUTOMATIC MEASUREMENT OF QUALITY IN PROCESS PLANTS

AUTOMATIC control has been utilized by the process industries for many years; indeed, many commercial processes in use to-day could not function efficiently without its aid. Over the past decade, however, the basic philosophy of automatic control has undergone a marked change as a consequence of the introduction of powerful new instrumental techniques. The function of automatic controllers has hitherto been that of regulating certain basic parameters of a process, in the hope that adherence to fixed values of such parameters—temperature, flow or pressure—would result in an end-product of unvarying quality. The analysis of the end-product has, of necessity, been carried out in laboratories remote from the plant, with the consequent introduction of long delays between the detection of variations in the end-product quality and the initiation of the appropriate remedial action on the plant itself. The economic benefits which could be obtained by carrying out such analyses directly on the process stream have stimulated the development of a wide variety of instruments for the purpose, many of which have passed the experimental stage and are now accepted as sufficiently reliable for plant use.

The Society of Instrument Technology is to be congratulated on its choice of "The Automatic Measurement of Quality in Process Plant" as the subject of the 1957 Conference, which had as its aim the bringing together of research workers, instrument engineers and other workers in this field to discuss these developments and their common problems.

Membership of the Conference, which was held at University College, Swansea, during September 23–26, was restricted in order to promote informal discussion; it is noteworthy that a number of the Conference members were drawn from the United States, Germany, Holland, Norway and the U.S.S.R., so that the open discussions provided an international forum for the exchange of ideas.

The seven formal sessions of the Conference fell into two complementary groups; a number of papers were devoted to a review of the experience which has been gained with established instruments, while the second group explored the possible plant application of analytical techniques at present utilized only in the laboratory. In addition to the formal technical papers—which will be published with their associated discussions by Butterworths Scientific Press—the Conference heard two informal talks which related its main topic to fundamental issues. Prof. D. P. Eckman considered the basic problem of the optimization of control by on-line computation, while another guest speaker, Dr. W. P. Colquhoun, drew an illuminating comparison between the human senses and automatic instrumentation.

The opening session of the Conference was concerned with the adaptation of laboratory techniques to plant measurement. Laboratory analytical techniques are, for the most part, well established and well understood; it is natural to suppose that an automatic analysis can be carried through by the mechanization of the laboratory method, although such methods are often based on a sequence of discrete measurements and so are not readily adaptable to truly continuous operation. This point was stressed in E. Hodgson's paper, which described an instrument for the determination of the crystallizing point of batch samples. It is clearly advantageous to know the composition of a plant stream throughout the course of a reaction, rather than to know its composition at intervals, and it is therefore an obvious, if difficult, step to make the analysis continuous.

Three papers, which were presented in the following session, described the manner in which this further step had been accomplished for calorimetric measurements on town's gas—a measurement of considerable importance to the gas industry, which is bound by law to maintain certain standards of calorific value and purity in the gas supplied to consumers.

Considerable discussion was aroused by another of the papers presented in this session, in which the authors underlined the difficulty of securing representative samples of gaseous streams—a problem which, it is often said, is more difficult than the analysis itself. It is significant that this theme recurred frequently in papers devoted to a wide range of analytical techniques.

The need for continuous control has resulted in the extensive use of physical methods of analysis; this trend was reflected in the eleven papers, presented on the second day of the Conference, which reviewed the use of such diverse methods as mass spectrometry, vapour phase chromatography and refractometry.

Three of the papers were devoted to existing instruments working in the visible and infra-red region of the electromagnetic spectrum. Infra-red analysis is now well established as a process technique, in spite of the fact that it is often difficult to find completely characteristic absorptions, and considerable overlapping of the spectra is common. In practice, of course, such imperfections are overcome by corrective procedures, but it is clear that the fundamental power of the method would be greater if it were possible to obtain narrower absorptions and higher resolution. These features are characteristic of microwave spectra, which are also very sensitive to molecular structure. The potentialities of microwave spectroscopy in process control analysis were considered in a paper by Dr. J. Sheridan; a second paper, read by Dr. R. E. Richards, described yet another relatively new branch of chemical spectroscopy—nuclear magnetic resonance, which may well be applied to process stream analysis, although little published information is available on its industrial applications. To the plant engineer, perhaps, these techniques may appear to be too difficult and complex for eventual adaptation to plant use. He would, however, do well to ponder on the implications of the final paper of the day, read by Dr. E. T. Hall. Dr. Hall is well known to the archæological world for his work on the dating of antiquities by the analysis of their chemical composition. In the course of his research (which has included, among other achievements, the detection of the Piltdown skull forgery) Dr. Hall developed an X-ray fluorescent analysis instrument, which is to be manufactured commercially for process use.

The last session of the Conference was devoted to a review of the uses of radioactive isotopes in quality measurement and a stimulating paper by Prof. W. Fishwick, which provoked considerable discussion, on the possibilities of analysis by physical measurements of an out-of-the-ordinary character. The session ended with an open discussion on the engineering design of instrumentation.

The catholic nature of the papers given at this Conference was in itself an indication of the rapidity with which technologists adapt to their own problems the tools provided for them by research workers in other fields; it is obvious, nevertheless, that the transition from research tool to plant instrument is difficult and expensive. It is essential that an instrument for plant use should function reliably for long periods without attention, and that maintenance should be reduced as far as possible to standard procedures, so that it may be carried out by relatively unskilled personnel.

The development of such instruments must at the same time be accompanied by the development of the associated sampling systems, since both are essential to the successful operation of the analyser on the plant. It is evident that a great deal of effort is at present expended on the design of sampling systems to meet the needs of various sectors of the process industries, each of which must therefore devote in isolation technical man-power to problems which must, in many cases, share many points of similarity. The consequent inefficient use of skilled technologists might well be remedied by the adoption of some coherent plan of attack which would co-ordinate the efforts of both users and manufacturers, both of whom were represented at the Conference; it is to be hoped that the Society of Instrument Technology will act on the suggestion, so well received by the Conference, that the time is ripe for it to establish a working team to codify existing knowledge on sampling techniques and to correlate development work in this field.

SCIENCE IN UNITED STATES UNIVERSITIES

A SURVEY of scientific research activities at colleges and universities in the United States, published by the National Science Foundation as No. 6 of "The Reviews of Data on Research and Development", gives the number of scientists and engineers employed in the natural and social sciences during the academic year 1953–54 as 70,000.

Detailed information was obtained from 180 out of 190 institutions constituting almost all the schools granting advanced degrees in science, and more limited information was obtained from 807 out of the remaining 930 schools. The returns covered 62,251 or 90 per cent of the total, and of these 31,435 were engaged in research, 8,262 being full-time, the total full-time equivalent being estimated as 16,534. Of these latter, 5,481 were engaged in research (2,281 in engineering sciences, 1,077 in chemistry, 837 in physics), 3,508 in biological sciences, 2,171 in chemical sciences, 3,658 in agricultural sciences, 389 in psychology, and 1,327 in social sciences.

The 180 larger institutions reported 24,000 supporting personnel, corresponding to a full-time equivalent of 15,060, giving a ratio of approximately 1 : 1. Of the 46,500 faculty members in the natural and social sciences at the 180 larger institutions, about 37,500 were employed full-time, and two-thirds of all the faculties spent some time on research, representing two-fifths of the total faculty-time, whereas in 807 small institutions less than 2 per cent of faculty-time was devoted to research, less than 10 per cent, or 16,000, employed being engaged in research.

Nearly 1,500 professional schools were reported by the 987 institutions, of which 764 were in arts and sciences, 131 engineering, 106 health, 71 agriculture, 217 research organizations (mainly responsible for a particular field of research) and 263 other professional schools. Two-thirds of the institutions were private and the remaining public-controlled institutions employed 56 per cent of the total engaged in the natural and social sciences, 61 per cent of which were engaged in research.

STARLING ROOSTS

A FASCINATING account of the way in which starlings roost and the sites they choose has been given by H. A. S. Key in the *Bedfordshire Naturalist* (11 ; 1957). Starlings are abundant in Bedfordshire, and the many resident birds are considerably augmented during the winter months by many thousands of others which arrive chiefly from Scandinavia. At night the birds congregate in communal roosts which are usually sited in thorny copses and spinneys. In general, once a roost has reached an optimum condition of growth and non-disturbance, it is used for many seasons. At each roost the pattern of assembly is much the same. The birds fly at first in leisurely stages towards the roost, but as the daylight fades and they get nearer to the point of assembly, their flights are more direct and flocks tend to converge and amalgamate.

The point of assembly is close to the roosts and often on the ground, where the birds form a dark carpet and the noise of their whistling and chattering is considerable. Then, suddenly, they get up, often indulging in some preliminary aerobatics, first in extended and then in close formation, before the entire party moves in a steady stream into the roost proper. Here with a great deal of commotion they wheel around and settle on the trees. For a short period there may be changes of perching areas within the roosting wood, but finally, when it is almost dark, the whole mass of birds is assembled in the regularly used part and then as each stem becomes packed with the jostling mass the din reaches its crescendo. From this tight grouping they are then not easily disturbed and sharp noises such as hand-clapping usually only suffice to cause the nearest group to move a few yards away.

In north Bedfordshire it would appear that the majority of the birds frequent one or other of two very large roosts, the populations of which would be hard to determine. These are Horn Wood, near Bozeat, Northants, just outside the west boundary of the county, and another site near Everton in the east. There was some years ago a smaller roost in Keysoe Park Wood, but this seems to have been abandoned.

THE NATIONAL TRUST

ANNUAL REPORT, 1956–57

THE sixty-second annual report of the National Trust, for 1956–57, makes slight reference to the threats offered to its primary duty of ensuring the safety of fine open country or fine buildings which arise from Government departments or other public authorities. Some evidence is recorded of increasing public appreciation : in 1956 nearly 900,000 visitors paid for admission to those properties where an entrance fee is charged, an increase of more than 200,000 on 1955, and membership increased by more than 5,500 to 61,713, with a further increase of 3,740 during the first seven months of 1957.

Nevertheless, the Council's hope that the 100,000-mark will be reached in 1959 seems modest indeed and far too low, either to relieve the Council of continuing financial anxiety (in spite of a small surplus in 1956, when membership income increased by £17,000) or to ensure the widespread public understanding and support necessary to avert the increasing destruction and vulgarization of the countryside, country towns and villages. While the position of the country house to-day seems slightly less gloomy and in archaeology a considerable sum has been spent in the past eighteen months on the preservation of the Cerne Giant in Dorset, repairs have been commenced to the Roman ruins at Ribchester, and satisfactory progress is reported in repairs to the Roman wall at Hotbanks, the report expresses the opinion that the face of England is rapidly changing for the worse.

Cafés, petrol stations, advertisements, neon lights, concrete lamp-standards, ill-sited and ill-designed, are everywhere, and persistent irresponsibility is shown in siting high-power cables, nuclear power stations and radar installations. The Trust has protested more than once during the past year against such ill-considered siting, but although this desecration is viewed with anxiety and regret the Council believes that a change of faith in official quarters and the establishment of a new canon of taste could, even now, save the situation and repair much damage already done. The Council appeals to members for active support in its practical proposals for dealing with the development of the English landscape, and in particular the report urges the importance of reducing signposts to the essential minimum and for far more thought in their design and siting.

GROWTH AND REPRODUCTION IN WORM-FREE SHEEP AT PASTURE

By Dr. C. R. W. SPEDDING, T. H. BROWN and I. A. N. WILSON
Grassland Research Institute, Hurley, Berkshire

NEMATODES parasitic in the alimentary tract have been shown to cause a depression of the growth-rate of lambs maintained indoors[1,2] even when the level of infestation has been sub-clinical. This has been confirmed for lambs at pasture[3], and it has been found possible to raise lambs free from stomach and intestinal worms (with the exception of *Strongyloides papillosus*) by rapid folding over clean pasture[4].

Thirteen Suffolk × half-bred ewe lambs reared with their infected ewes in this way in the spring of 1956 were weaned on to 6 acres of worm-free pasture (that is, one not grazed by ruminants for at least two years) in June of that year. They remained on this area, for the most part set-stocked, until April 1957, with the exception of three weeks (Oct. 29–Nov. 23, 1956) when they were brought indoors to be tupped. This procedure was necessitated by the absence of a worm-free ram. At the same time, 15 of the best remaining ewe lambs from the farm flock were selected for comparison. The previous live-weight history of these two groups is shown in Fig. 1. The decline in live-weight gain of the infected ewe lambs (Group *I*) during the autumn was characteristic of sheep of that age on the farm and occurred in spite of grazing a better pasture than that available to the worm-free lambs (Group *F*). Thus, at tupping time, Group *F* lambs were, on average, 17 lb. per head heavier than those in Group *I*. The latter were maintained throughout the tupping period on a nearby field, and the same ram was employed for both groups, spending the day in the field and being brought in to Group *F* at night.

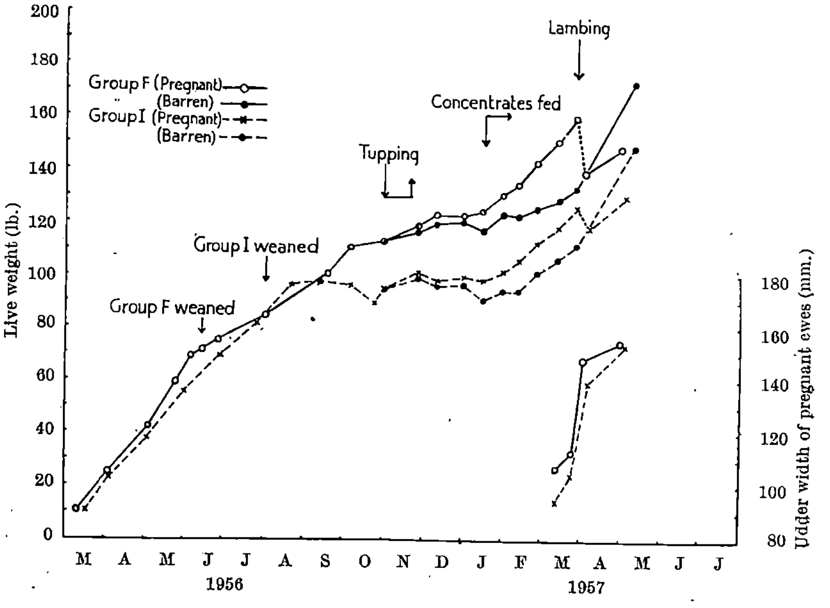

Fig. 1. Mean live weights and udder measurements of Groups *I* and *F*

On November 23 Group *F* was returned to its field, and Group *I* was grazed on a comparable, and at no time inferior, sward. Fig. 1 shows the subsequent mean live-weight changes for both groups of sheep. From January 16, 1957, concentrates (80 per cent cereal, 15 per cent dried lucerne meal, 5 per cent linseed cake) were fed to both groups at the rate of ¼ lb./head/day, rising gradually to 1 lb./head/day on February 25 and continuing at that rate until April 24. A mineral mixture rich in magnesium was included to prevent hypomagnesæmia.

The egg counts for each group are shown in Fig. 2. The egg-count curve for Group *I* was typical of sheep of that age at that time, but rather low. Group *F* fæces were negative for parasite eggs until the sheep were brought inside for tupping, when a mean count of 2 eggs per gm. was recorded. This declined to

† Numbers of animals are given in brackets.

zero and remained so until lambing time, when eggs again occurred. This shows that Group *F* carried a few worms which, at times of stress leading to a temporary lowering of resistance, produced measurable numbers of eggs. The parasitological consequences of this to ewes and lambs will be dealt with elsewhere.

Since it is not possible to prove that any group of living sheep has no worms at all, it has been suggested[5] that a 'worm-free' sheep be defined as one that normally shows no evidence of infestation even when set-stocked on pasture with every opportunity for re-infection. In this sense Group *F* were worm-free over the year considered here. The live-weight gain of the ewes from tupping to lambing included any differential growth of fœtus and maternal tissue: the mean difference in live-weight just before lambing on March 26, 1957, was 32 lb./head in favour of Group *F*. The ewes were weighed within 24 hr. of lambing, however, and the gain in body-weight has been calculated for the period from tupping to this post-lambing weight (Table 1). At intervals during late pregnancy and lactation, udder-widths were measured on all the ewes, the width being the distance across the teats measured externally at the base of the teat. Group *F* udder-widths exceeded those of Group *I* by 6·5 per cent at lambing time (Fig. 1).

The birth data for the lambs produced by both groups are given in Table 1. Group *F* produced significantly heavier single lambs ($P < 0 \cdot 01$) than Group *I*; there were fewer barren ewes and lower mortality. Two lambs in Group *F* suffered from mis-mothering and had to be removed; one of them died later. There was no difference in the length of the gestation periods. There were too few twins to make a meaningful comparison of their weights or growth.

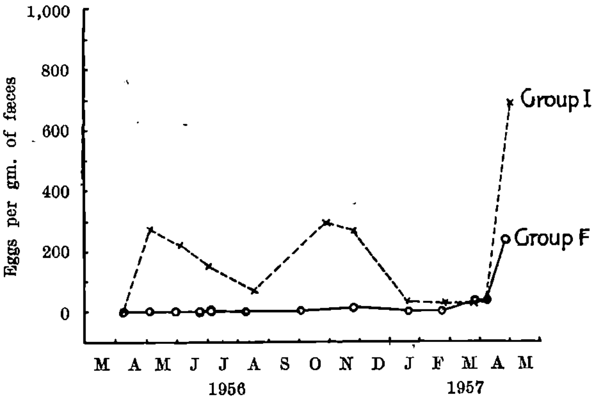

Fig. 2. Mean egg-counts of Groups *I* and *F*

The arrangements for tupping were of necessity restrictive and preclude a valid comparison of lambing percentages. The differences observed in the birth-weights of the lambs may be attributed either to the presence and absence of worms over the whole life of the ewe or merely during pregnancy. Worm-infestation before pregnancy resulted in a mean difference of 17 lb. per head in November. There was, however, no correlation between the weights of the ewes at tupping time and the birth-weight of their lambs in either Group *I* (with a range of 17 lb. in ewe weights) or Group *F* (with a range of 30 lb.). Moreover, infected ewes produced considerably lighter lambs than worm-free ewes of comparable weight at tupping time. Thus it seems unlikely that the lower lamb weights can be attributed to the fact that the infected ewes were lighter when mated. The number of twins was small, but the ewes that bore twins were among the heaviest in each group.

The infection carried by Group *I* ewes during pregnancy, although light in terms of fæcal egg counts, was clearly the major factor. The non-pregnant ewes of Group *F* gained 31·4 per cent more weight during the winter period (October 29, 1956–March 26, 1957) than those of Group *I*; numbers were small, however, and this difference was not statistically significant. The growth of the in-lamb ewes of each group from tupping to lambing (based on immediate post-lambing weights) was the same. The effect of worm-infestation was therefore just over 30 per cent in both non-pregnant and pregnant ewes but in the latter it affected only the fœtus and the associated maternal tissues. In Group *F* the pregnant ewes carrying singles gained slightly more body-weight than the non-pregnant animals; in Group *I* the difference was much greater, though not statistically significant. Thus the effect of worm-infestation appeared to be greater on barren than on in-lamb ewes and did not affect the growth of the latter, except in a reproductive sense. The growth of the pregnant ewes of Group *I*, in fact, was equal to that of Group *F* and appears to have taken complete priority over the growth of the fœtus.

The udder-width measurements differed by 6·5 per cent, which might indicate a lower capacity to produce milk. This suggestion was supported by the growth of lambs from birth to 28 days old: single lambs in Group *F* gained 6·8 per cent more weight during this period. These differences were not statistically significant; but it should be noted that the majority of Group *F* single lambs were female (6 out of 7) while the majority of Group *I* lambs were male (5 out of 7). There was no correlation of birth-weight with growth to 28 days in either group.

Twenty-eight days after the birth of the lambs, therefore, Group *F* single lambs were 11·3 per cent heavier than those of Group *I*; the barren ewes were 16 per cent heavier and the ewes suckling single lambs were 13·8 per cent heavier in Group *F*.

This suggests that the effect of a moderate degree of worm infestation on the growth of ewes is similar to that found for other sheep[3] but that in pregnant ewe lambs the effect may be suffered entirely by the developing fœtus and the associated maternal tissues.

We wish to thank Dr. William Davies for facilities granted, Mr. C. D. Kemp for the statistical treatment of the results, and Mr. J. E. Betts for technical assistance.

LOCALIZED ELECTRONS IN BODY-CENTRED CUBIC METALS

By J. S. GRIFFITH and L. E. ORGEL
Department of Theoretical Chemistry, Cambridge

IN this article we gather together experimental evidence supporting a recent idea about the electronic structure of body-centred cubic transition metals proposed by one of us[1] and developed by the other[2]. A closely related theory has been given independently by Stevens[3]. We suggest, essentially, that the valence orbitals on a given metal atom can be divided into two classes, the orbitals of one of which bond strongly with the rest of the lattice, and those of the other only weakly.

In a body-centred cubic metal each atom is surrounded by eight others at the corners of a cube, so that the site symmetry is cubic. We discuss at first the metals of the first transition series as most of the experimental data refer to them, although a qualitatively similar discussion would apply to the other two series. The $3d$-, $4s$- and $4p$-orbitals are then the important valence orbitals, the $4f$- and other orbitals probably making only a minor contribution to the cohesive energy. Under the cubic group these orbitals form bases for representations the irreducible components of which are shown in Table 1 (in the usual notation, see ref. 4). The main bonding interaction is presumably the σ-interaction between nearest neighbours. Table 1 shows that the s-, p- and $d(t_{2g})$-orbitals can take part in this, but that the $d(e_g)$-orbital cannot. (The $f(a_{2u})$ and $f(t_{1u})$ but not the $f(t_{2u})$-orbitals can also take part in σ-bonding but we shall not consider f-orbitals here.)

If we take rectangular Cartesian axes centred at a site and parallel to the cube edges, then the nearest neighbour nuclei lie along the directions of the eight vectors (±1, ±1, ±1). The two d-orbitals of the e_g representation are then d_{z^2} and $d_{x^2-y^2}$ and each has zero amplitude along all the nearest-neighbour directions. This shows in a more immediate way that they cannot σ-bond along any of them. A consideration of the angular variation of s, p and the three t_{2g}-orbitals (d_{xy}, d_{yx}, d_{zx}) shows readily that the σ-interaction allowed by group theory should really be large provided that the radial functions allow sufficient overlap. Hence, to the approximation of considering only σ-interaction with nearest neighbours, the seven valence orbitals $4s$, $4p_x$, $4p_y$, $4p_z$, $3d_{xy}$, $3d_{yz}$, $3d_{zx}$ bond and are able to hold the metal together, while the two orbitals d_{z^2} and $d_{x^2-y^2}$ are entirely non-bonding. We call the former class 'bonding orbitals' and the latter class 'localized orbitals'.

Table 1. REPRESENTATIONS SPANNED BY ATOMIC ORBITALS AT A SITE AND NEAREST NEIGHBOUR AND NEXT-NEAREST NEIGHBOUR σ- AND π-ORBITALS IN A BODY-CENTRED CUBIC LATTICE

Atom	Orbital	Representations
Site atom	s	a_{1g}
	p	t_{1u}
	d	$e_g + t_{2g}$
	f	$a_{2u} + t_{1u} + t_{2u}$
Nearest neighbour	σ	$a_{1g} + a_{2u} + t_{1u} + t_{2g}$
	π	$e_g + e_u + t_{1g} + t_{1u} + t_{2g} + t_{2u}$
Next-nearest neighbour	σ	$a_{1g} + e_g + t_{1u}$
	π	$t_{1g} + t_{1u} + t_{2g} + t_{2u}$

It may clarify matters to relate our treatment to those postulating hybrid σ-bonds directed towards the corners of a cube (that is, towards the nearest neighbours). Van Vleck[5] showed that it is possible to construct eight equivalent hybrids from $sp^3d^3f^1$. Here the f-orbital is f_{xyz} (or a_{2u}) and the remaining seven are our bonding orbitals. The two d-orbitals which cannot be used in these hybrids are our two localized d-orbitals. Thus in Pauling's resonating-bond model[6] for a body-centred cubic metal the resonating bonds are formed only from our bonding atomic orbitals and never from localized ones.

If we include π-bonding and next-nearest neighbour interaction in our theory the distinction between the two classes of atomic orbitals is no longer complete. The e_g-orbitals can π-bond with the nearest neighbours and σ-bond with the next-nearest neighbours (this latter circumstance is to be related to the possibility of constructing octahedral sp^3d^2 σ-hybrids). The other orbitals also have extra bonding possibilities, as one sees from Table 1 (in an earlier paper (ref. 1, Table 2) the nearest neighbour π-interaction of the $d(t_{2g})$ orbitals was incorrectly omitted). However, the general conclusion that the seven 'bonding' orbitals are relatively strongly bonding while the two 'localized' orbitals are only weakly so should still hold.

The discussion we have given so far suggests that one should regard the two localized orbitals in the same way as one regards inner shell orbitals, or $4f$-orbitals in rare-earth metals. In other words one should assign a definite integral number of electrons (the same for each site in the metal) to the set of localized orbitals at each site. Denoting a bonding atomic orbital by b and a localized one by l, this means that we assign a definite configuration $b^m l^n$ to each body-centred cubic metal, with $(m+n)$ the number of valence electrons and m and n yet to be determined. Here n cannot be greater than four, by the Pauli exclusion principle.

For $b^m l^1$ or $b^m l^3$ we have the localized electrons at any site forming a component of a ^2E_g state; for $b^m l^2$ the pair of localized electrons could belong to

Table 2. CONFIGURATION ASSIGNMENTS FOR BODY-CENTRED CUBIC FIRST TRANSITION-SERIES METALS
Hypothetical body-centred cubic metals in brackets

Metal	K	(Ca)	(Sc)	Ti	V	Cr	Mn	Fe	(Co)
Configuration	b^1l^0	b^2l^0	b^3l^0	b^4l^0	b^5l^0	$b^{5-6}l^{1-0}$	b^6l^1	b^6l^2	$b^{6-7}l^{3-2}$

$^3A_{2g}$, $^1A_{1g}$ or ^1E_g states. Using Racah's notation[7], the $^3A_{2g}$ state lies lowest in energy, with the ^1E_g state lying $(8B+2C)$ above and the $^1A_{1g}$ state the same amount higher still. The symbol b^m refers to a situation which cannot be described in any simple fashion. If there are N metal atoms, the mN bonding electrons could, of course, be assigned to bands formed from bonding orbitals. This would, however, involve an approximation introduced only for ease of calculation, but which is not implicit in our model. Our assignment of the configuration symbol b^ml^n merely implies that in the metal mN electrons are in bonding atomic orbitals (we allow polar structures for b^m but not for the localized electrons) and that on each site n electrons are in localized atomic orbitals.

In principle, to describe a metal with two localized electrons one should take the best linear combinations of functions each of which is a product involving $^3A_{2g}$, $^1A_{1g}$ or ^1E_g states at each site. One could not then say that l^2 at a given site and for a given total electronic function is a definite one of the possible site states $^3A_{2g}$, $^1A_{1g}$ or ^1E_g. However, one would naturally expect the lowest eigenfunctions based on configurations b^ml^2 to correspond to states which are almost entirely $^3A_{2g}$ at each site, and this is an assumption of our theory.

The next problem is to decide what the individual values of m and n are. At the beginning of a period, one expects the electrons to go into the bonding orbitals. Thus body-centred cubic potassium would be b^1l^0. It would be difficult to decide from *a priori* considerations when the electrons start going into the l-orbitals. If one accepts our model, however, the experimental data for the first long period strongly suggest that the first six electrons go into b-orbitals and then the l-orbitals start filling up at least until two electrons are in them. The configurations we propose for body-centred cubic metals, then, are shown in Table 2.

In a more complete discussion we would consider interconfigurational interactions. To have a complete set of basic configurations we would include structures having different numbers of localized electrons on different sites. Our proposal is, however, that we may usually restrict attention to one of the special configurations b^ml^n without great inaccuracy. We shall find that the magnetic evidence may indicate a mixture of configurations for chromium, and then, of course, the majority of low-lying states will be linear combinations of functions corresponding neither to b^6l^0 nor to b^5l^1, but of functions corresponding to $n=0$ on some sites and $n=1$ on others.

We now pass on to show how the experimental data accord with our model and the above assumption about the individual values of m and n.

Magnetic Properties

Neutron diffraction experiments[8] on vanadium do not indicate any magnetic moment. This we interpret to mean that vanadium has the configuration b^5l^0. Chromium[8], however, appears to have a small moment per atom, although the experimental position is not quite clear. This perhaps justifies the symbol $b^{5-6}l^{1-0}$ in Table 2. We regard the low-lying states of chromium as being formed from structures with no localized electron on most sites and perhaps with one on others.

Body-centred cubic iron is ferromagnetic with a saturation magnetization of 2·22 μ_B per site. Neutron diffraction confirms this figure[8]. It has been interpreted by supposing there are two electrons with parallel spins on each atom which then align ferromagnetically by an indirect interaction through a conduction band[9]. This interpretation, according to our point of view[1], means that iron is predominantly b^6l^2. The two localized electrons on a given site have their spins parallel because the lowest state of l^2 is $^3A_{2g}$. The 'conduction band' is roughly equivalent to b^6 in our model.

In view of the analogy between our localized d-orbitals and inner-shell $4f$ rare-earth orbitals, this model of ferromagnetism in iron is precisely analogous to the model for ferromagnetic gadolinium with the configuration b^34f^7 in which the localized $4f$-electrons carry the magnetic moment.

Electron Distribution

The spatial distribution of electrons in transition metals has been studied by Weiss and co-workers[10] using X-ray methods. They find that for face-centred cubic nickel and copper the electron density corresponds to an inert gas core together with the anticipated number of d-electrons (ten in copper and about nine in nickel) each having a radial distribution similar to that given by Hartree–Fock calculations. However, in body-centred cubic chromium there is no evidence at all for d-electrons with a normal radial distribution, while for body-centred cubic iron the electron density corresponds to the core and just two normal d-electrons.

The absence of any density corresponding to d-orbitals in chromium is very puzzling. Presumably the radial functions for the electrons used in bonding are very different from those in the free atom and so escape detection by the X-ray method. However, the presence of just two radially localized electrons in iron is nicely consistent with the suggestion that there are two non-bonding electrons present in the e_g orbitals[1], since a non-bonding electron would be expected to have a radial distribution not too different from that in the free atom.

The low-temperature phases of both chromium and iron are body-centred cubic, but while there is a body-centred cubic form of manganese at high temperatures the low-temperature manganese structures are very complicated. It has been suggested[2] that this is because in the configuration b^6l^1 anticipated for body-centred cubic manganese the localized electron in the doubly degenerate e_g-orbital would lead to a Jahn–Teller distortion of the lattice. Considered alone, this evidence would, of course, be very indirect.

X-ray Spectra

Finally we discuss the soft X-ray spectra of body-centred metals. Our theory would lead us to anticipate that the allowed transitions from the $2p$- and

$3p$-orbitals to the $3d$- and $4s$-orbitals would show one remarkable feature, namely, the presence of relatively narrow bands corresponding to transitions to the $3d(e_g)$-orbitals[2]. Furthermore, in chromium, since the e_g-level is just about to fill up, we should expect the narrow band to lie at the absorption edge. In iron, on the other hand, two electrons are already in the e_g-orbitals so that a third would be forced to go in with antiparallel spin. It follows that the most stable empty orbitals are bonding orbitals, so that the narrow absorption band should be preceded by some absorption involving transitions to the conduction band. Both these anticipated features have been reported in the M_{II} and M_{III} spectra of chromium and iron[11], but no explanation of them has previously been given.

It is perhaps necessary to remark that the X-ray spectra give the relative positions of different unoccupied orbitals only in a qualitative sense. The excitation of an inner electron increases the effective charge on the nucleus and so perturbs the energy-level scheme of the metal. If different orbitals are perturbed to different extents, the relative positions of these orbitals may be modified. In particular, a localized orbital will be more affected than an orbital which is part of a broad band, so the stability of the e_g-orbital will be exaggerated somewhat in the X-ray spectrum. The difference between chromium and iron, however, is unambiguous.

Additional Data

There is not much to say about the later transition series. Neutron diffraction indicates no atomic magnetic moments for niobium, molybdenum or tungsten, suggesting the configurations b^5l^0, b^6l^0 and b^6l^0 respectively.

In the second and third series the last element to have the body-centred cubic structure is that in group VI[12]. In the first period, however, iron has both this structure and a close-packed structure[12]. Now body-centred cubic iron has a stabilization of about 9 kcal./mole due to the exchange energy between the two l-orbitals[1], there being no such exchange energy in close-packed iron. Since the two structures are almost equi-energetic[13] one must suppose that there is a compensating gain of bonding energy in the close-packed structure. Accepting this empirical balance, one then expects the body-centred cubic structure to be less stable relative to close-packed structures for ruthenium and osmium because one knows that the exchange integrals (from atomic spectral data) are smaller, and the overall cohesive energies (and hence presumably bonding energies in the limited sense) are larger. Although ruthenium and osmium are hexagonal close-packed, whereas iron is face-centred cubic, one may still suggest that the fact that only iron of the group VIII metals forms a body-centred cubic structure is due to the two reasons given.

In neither the hexagonal nor the cubic close-packed metal lattices is it possible to find any s-, p- or d-orbitals which do not interact in a σ-fashion with nearest neighbours. Hence our discussion does not apply directly to them. This means that the ferromagnetism of cobalt and nickel cannot be discussed in the same way as that of iron.

ORIGIN OF TEKTITES

H. H. NININGER[1] has proposed that tektites be regarded as the ejecta from lunar craters produced by meteorite impact. He points to the work of L. J. Spencer[2,3] comparing the tektites with glassy matter from terrestrial meteorite craters. The wide distribution of tektites of a single type, such as australites, argues in favour of lunar rather than terrestrial craters.

This theory is especially attractive because there appears to be direct evidence that spherical glassy bodies have been ejected from some of the ray craters. The evidence is the fact that long bright streaks diverge from these craters ; and that these streaks appear to return light in the direction from which it came in the manner of a beaded-glass screen[4]. (Prof. M. Minnaert has informed me verbally that experiments at Utrecht on various surfaces have shown that the dependence of brightness on phase angle observed for the bright rays cannot be duplicated by plausible sorts of surfaces ; but can be duplicated by scattered glass beads.) Furthermore, in at least one case, namely, Tycho, the streaks extend almost half-way around the Moon, and hence correspond to velocities of the order of the velocity of escape from the Moon.

Nininger seeks to explain the distribution of tektite finds, chiefly within 40° of the equator, as a consequence of lunar origin, the tektites having followed, he believes, a direct line between the centres of the Moon and Earth, and arriving in the tropics because the Moon is overhead only in these latitudes. This explanation is not satisfactory, since it assumes implicitly that the orbital velocity of the Moon is perfectly cancelled by the explosion velocity. If the cancellation is imperfect, the orbital plane will be determined by the centre of the Earth and the resultant velocity vector, and will be oriented more or less at random.

This difficulty can be removed if we assume that the Earth possesses an outer atmosphere, extending 10 radii or more, and having a density of the order of 10^{-21} gm./cm.^{3}. (Dr. H.-K. Paetzold, of the Max-Planck-Institut, has verbally confirmed this order of magnitude of the density of the atmosphere at 10 Earth's radii.) In this case, many of the particles thrown from the Moon could be expected to encounter the extended atmosphere near perigee. The effect of the atmosphere will be to diminish the eccentricity and semi-major axis of the orbit of the particle around the Earth[5].

After a period of 10^7 years or the like, the orbit would become very nearly circular, and would approach the surface of the Earth. Owing to the attraction of the equatorial bulge of the Earth, the orbit would be more sharply curved where it crosses the equator. The equations of motion have been integrated for a closed, almost circular orbit which is symmetrical about the Earth's axis. It is found that the radius vector, r, can be expressed approximately as a function of the latitude φ for a meridional orbit by the relation:

$$r = r_0\left(1 + \frac{\alpha}{12}\cos 2\varphi\right)$$

where α represents the flattening of the Earth. On the other hand, the sea-level surface of the Earth can be described by the corresponding relation

$$r = r_0\left(1 + \frac{\alpha}{2}\cos 2\varphi\right)$$

It is seen that the orbital perturbations cancel only one-sixth of the effect of the Earth's ellipticity. It follows that such a satellite will be about 11 miles nearer the surface of the Earth at the equator than at the poles, and will be subjected to about fifteen times as much air resistance. It will thus nearly always come to Earth in latitudes near the equator, in accordance with the distribution found for tektites.

An example of a body describing such an orbit is provided by the meteor procession of February 9, 1913, described by C. A. Chant[6] and computed by the Rev. M. A. Davidson[7]. This group of bodies described a path 5,700 miles long from Saskatchewan to the South Atlantic at heights of the order of 40 miles. The orbit was clearly a nearly circular one about the centre of the Earth. W. J. Fisher[8] suggested that the bodies were intercepted by the equatorial bulge of the Earth.

It thus appears plausible that in the tektites we have portions of the lunar surface.

The kind assistance and advice of Mr. E. P. Henderson, of the U.S. National Museum, is gratefully acknowledged.

ON the basis of observations accumulated by different authors over the past few decades, I consider that an extra-terrestrial origin of tektites is more compatible with their observed physical and chemical properties. The greatest difficulty encountered by any theory invoking an extra-terrestrial origin of tektites is to explain their peculiar distribution over the surface of the Earth. One would assume that, if tektites had arrived at the Earth in swarms, each swarm would have deposited them over one terrestrial hemisphere, unless the tektites were members of relatively small clouds. Since we observe the tektite deposits to be localized in small regions, we must conclude that the second alternative must be the correct one.

However, a cloud of such particles travelling through space would not retain any degree of compactness for more than a few hours, or perhaps days, and hence the cloud must have originated very near the Earth, possibly at the Moon. To test this hypothesis, I carried out a series of calculations which determined whether material ejected from the Moon by the impact of a meteorite on the lunar surface could arrive at the Earth in such a way as to reproduce the observed distribution of tektites on our planet. The initial conditions of ejection were chosen according to a model of meteoritic impact suggested by Whipple and Rinehart (unpublished work). The computations were carried out on the *IBM* 704 digital computer of the Massachusetts Institute of Technology. The distribution of tektites ejected from a lunar crater so computed agrees remarkably well with the observed distribution of australites (tektites found in Australia), thus making the Moon a very likely source for these peculiar objects.

Details of the calculations have been included in a paper submitted for publication in *Geochimica et Cosmochimica Acta*.

THE glassy nature of tektites requires an explanation in terms of the processes of the impact explosions. The heating at a meteoritic impact is very intense, due to the great compression of the meteorite and a comparable quantity of the material of the ground. During the short duration of the event, however, not much heat can be communicated to the surrounding materials. Surfaces can be heated at most to their evaporation temperatures, and the depth to which heat conduction can then cause melting in a few seconds is limited to some millimetres in most substances. The mass ejected from craters is thought to be large compared with that of the meteorites causing them. The suggestion made by O'Keefe to account for the high reflecting power of the 'rays' around the younger lunar craters and also of their interior surfaces would require a large proportion of all this ejected material to be glassy; and so would the idea of the lunar origin of tektites.

A process that can distribute energy more rapidly than heat conduction through the interior of an opaque solid is required for the explanation, and a large pressure pulse appears to be the only possibility. An impact explosion will no doubt be responsible for a shock wave in the solid. It will, however, be mainly a single pressure cycle, and this can be expected to cause melting only in substances that possess much hysteresis in their compression characteristics. The material must end up as a liquid after the pressure pulse if it is to form beads. Sand or powder of hard rocks would qualify, as there the application and release of high pressure can greatly increase the final density above the initial one. The volume integral of pressure around the cycle representing the work absorbed in the material will then be large. Also the great decrease in the compressibility that will occur when all the empty spaces have been filled will allow pressure waves of a wide range of intensity to be propagated and to leave similar amounts of energy behind in heat in the material. Without such a sharply non-linear compression characteristic of the material, a shock wave intense enough to produce melting at one range from its focus would produce evaporation at a slightly smaller range, and again only little of the material would be left in liquid form.

On the Earth, the phenomenon of liquefaction by impacts of meteorites in sand has been recognized: the so-called impactites display terrestrial chemical composition, with somewhat similar glassy appearance to the real tektites. But these have occurred in a small fraction of the recognized impact events; where impacts occurred in originally compact materials, only the broken-up forms of these materials seem to have been ejected from the craters.

The present suggested identification of the tektites would allow, therefore, of a judgment concerning not only the chemical but also the physical condition of the lunar surface material. Experimentation with tektite material may allow one to specify more precisely in what state it must have been before the impact. Presumably these considerations go together with the idea that dust covers a large proportion of the lunar surface.

A POSSIBLE BASIS FOR PHYTO-IMMUNITY

By D. H. TAYSUM

Rubber Research Institute of Malaya, Kuala Lumpur

IN studies on immunity in higher animals the most obvious analytical medium is blood. In plants, however, no such simple standard system is available; indeed, phyto-immunity is, in principle, difficult to formulate because plants have no blood. A variety of natural saps and juices have been suggested as agglutinating systems in previous literature (see, for example, Berridge[1]); the difficulty is to give *a priori* justification to any one system rather than another. What is required is a plant product continuously in contact with (bacterial) infection and demonstrating resistance to this infection over a reasonable portion of the life of the plant (say, 30 years, in the case of a tree). This article suggests that *Hevea* latex is such a system and records its agglutination reactions.

Early in 1956, a sterile box was constructed around a rubber tree (*Hevea brasiliensis*—an unselected seedling), and the latter tapped under aseptic conditions, the air space being irradiated by six ultra-violet germicidal sources (Fig. 1). (Details of this apparatus are to be published elsewhere.) It was found that sterile latex was not initially obtained; the latex vessels harboured bacteria to a depth of about 8 mm. This population could be removed by deep-sectioning. That this type of viable population exists in the vessels of many rubber trees has now been confirmed. It is possible to take latex from the interior of these vessels using a sterile hypodermic syringe and aseptic technique and obtain latex with a viable population of up to 10^5 bacteria/ml.

After each tapping, some 10^{10} viable bacteria develop on the tapping cut; at the following tapping, however, latex with about 10^6 viable bacteria/ml. is obtained, and of this figure some 90 per cent result from random external contamination by bacteria on the outside of the tree. The presence of the indigenous population of latex vessels and the

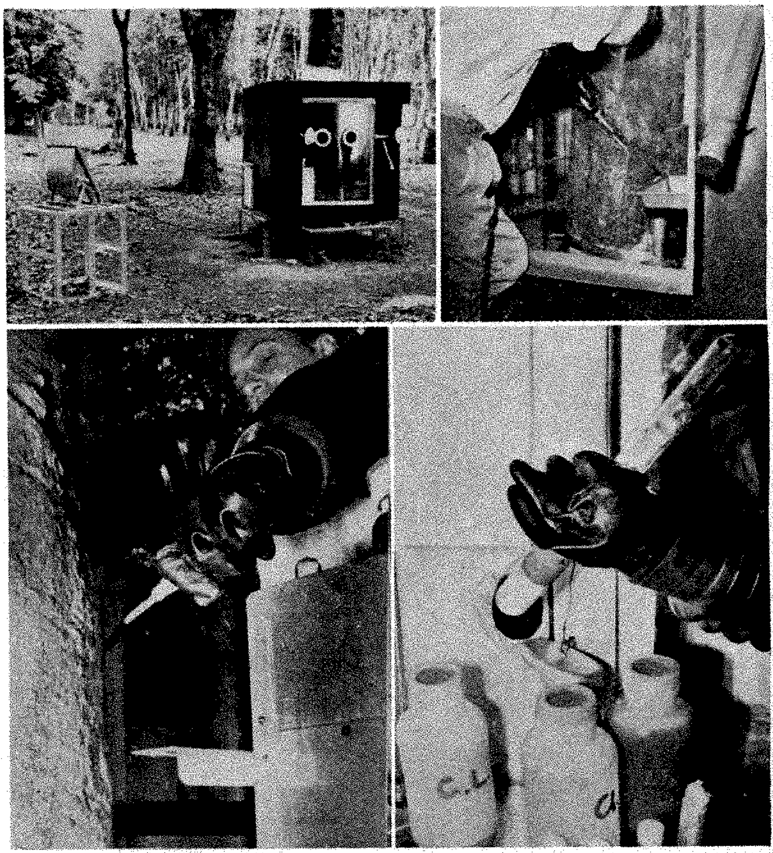

Fig. 1. Apparatus for tapping a seedling rubber tree under aseptic conditions; the sterile cabinet, the tapping operation and the removal of sterile latex in a sterile, sealed container through a dead-space are shown

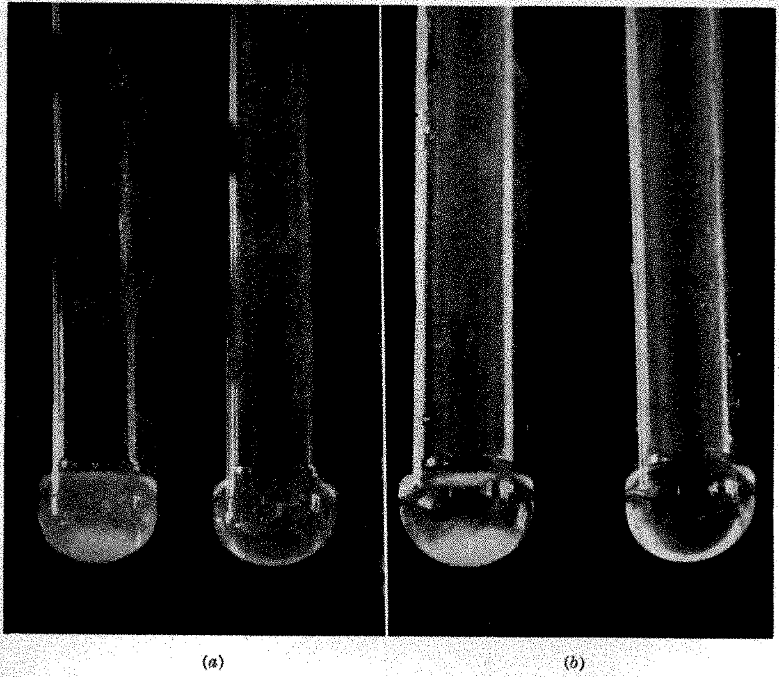

Fig. 2. Agglutination of bacterial suspensions by *Hevea* latex sera (53° C.). (*a*) Control suspension and agglutinated system for *Serratia marcescens* (Bizio). (*b*) Control suspension and agglutinated system for *Micrococcus* sp.

reduction in viable population achieved between tappings argue some powerful defence mechanism designed to limit bacterial attack. The most likely transport for this defence is latex itself (this does not exclude the possibility of a type of phagocytosis occurring elsewhere—say, in the plasma layer). Various types of antigen-antibody reaction could be suggested.

Fig. 2, *a* and *b*, shows agglutination of strains of *Serratia marcescens* (Bizio) and *Micrococcus* sp. both isolated from latex vessels; these are agglutinated by fresh *Hevea* latex sera from known (normal) infected trees, separated by high-speed centrifuging at 20,000 r.p.m. for 30 min. in rotor 40 of the 'Spinco Model *L*' ultracentrifuge (36,000 *g* maximum)[2]; the sera are filter-sterilized. Both somatic and flagellar agglutination are demonstrated by these sera. *H* agglutination takes about 40 min. at 53° C. and *O* agglutination some 8 hr. Despite the relative rapidity of these reactions, the titre is low, and almost neat serum is required for efficient agglutination.

Table 1. AGGLUTINATION REACTIONS IN BLOOD AND THEIR ANALOGUES IN *Hevea* LATEX

Designation	Blood system	*Hevea* latex analogue
Agglutination	Bacterial suspension in saline plus blood serum	Bacterial suspension in saline plus fresh latex serum (from centrifuge)
Hæmagglutination	Bacterial suspension in saline plus red blood cells	Bacterial suspension in saline plus *Hevea* latex hydrocarbon particles (resuspended)
Thomsen–Friedenreich panagglutination and bacteriogenic hæmagglutination	Agglutination of (bacterially) modified red blood cells by sera or other red blood cells (or the converse)	Agglutination of (bacterially) modified hydrocarbon particles by sera or other hydrocarbon particles from *Hevea* latex (or the converse)

In Table 1 are drawn up some normal agglutination reactions for blood, and these are compared to similar reactions obtained for *Hevea* latex.

Since the titre is low, non-specific agglutination might be invoked to explain the simpler reactions—by change of *p*H or by phosphate ion normally present in sera. This view is not favoured: fresh latex is almost neutral, mean *p*H 6·8, and the maximum difference between latices used in these experiments is 0·3 *p*H units; phosphate variations in seedlings are insufficient to explain observed variations in titre. Further, the analogue of bacteriogenic hæmagglutination is a particularly efficient reaction: hydrocarbon particles from virgin trees are rapidly agglutinated (and coagulated) by filter-sterilized infected sera; it therefore follows that some profound modification of these sera must have occurred as a result of previous infection. The difference in agglutination-rates between flagellates and non-flagellates is strong evidence in favour of a specific mechanism.

Of these reactions, those involving modified sera are well defined, there being no difficulty in detecting agglutination by eye; those involving hydrocarbon particles are weak when compared to hæmagglutination. Two factors contribute to this weakness: the first is the very small size of the hydrocarbon particle compared with the red blood cell (0·7μ as against some 8μ—a difference of about two thousand-fold in mass); the second is the low density of hydrocarbon. This means that agglutinated hydrocarbon particles with bacteria may either sediment or float in serum or saline, depending on whether a given clump is composed dominantly of bacteria or hydrocarbon; this does not facilitate macroscopic examination. It is believed that the Thomsen-Friedenreich and related phenomena may explain observations in which latex from newly opened (presumably uninfected) trees suddenly flocculates: contamination of this virgin latex with previously infected hydrocarbon or sera present in the tapping cup would initiate this process.

It is unfortunate that the gross contamination of trees in normal tapping results in these sera being polyvalent. Thus reaction to infection by single strains must be deduced from studies on previously unopened trees, with a resulting limitation in the number of experiments performed. Despite this difficulty, it is thought that these agglutination reactions of *Hevea* latex provide a general tool for the antigenic analysis of bacteria, particularly those pathogenic to plants.

This study forms part of a research programme on the microbiology of *Hevea* latex undertaken by the Board of the Rubber Research Institute of Malaya.

Electron Spin Resonance of Coals: Saturation Effect

In an investigation into the electron spin resonance of coal, I found a saturation effect depending on the percentage of carbon contained in the coal. The samples, all of them vitrinites, were examined in air; the frequency at which the measurements were made was 9,000 Mc./s.

It was found that in those cases where the saturation could well be measured the saturation factor Z showed good agreement with the theoretical expectation given by

$$Z = (1 + \tfrac{1}{4}\gamma^2 H_1{}^2 T_1 T_2)^{-1}$$

In this formula γ is the gyromagnetic ratio, H_1 the amplitude of the alternating magnetic field, T_1 the spin–lattice relaxation time and T_2 the spin–spin relaxation time. As Z, H_1 and T_2 could be experimentally determined, T_1 could be calculated.

Instead of T_1 Fig. 1 gives the variation of $P(Z = 0{\cdot}5)$ as a function of the rank. We define $P(Z = 0{\cdot}5)$ as that amount of energy dissipated in one gram of coal, for which the saturation factor Z becomes equal to 0·5. In some cases, for example, when measuring the number of free radicals, this quantity may have a more direct significance to the experimental investigator than the value of T_1.

A variation similar to that in Fig. 1 may probably be expected if for some sugar chars $P(Z = 0{\cdot}5)$ is plotted as a function of the carbonization temperature[1].

From Fig. 1 it is seen that at carbon percentages less than 88 the value of $P(Z = 0{\cdot}5)$ is very low, so that in determining the number of free radicals in this range there is a risk of measuring them in a saturated state and hence of finding a number which is lower than the actual one.

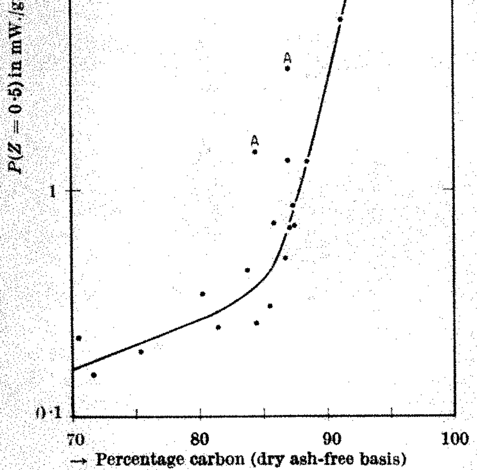

Fig. 1

At carbon percentages greater than 86 the value of $P(Z = 0{\cdot}5)$ shows a rapid increase. Lacking an energy source of sufficient power, I have not been able to measure the saturation effect beyond 94 per cent carbon. That the value of $P(Z = 0{\cdot}5)$ in this range must be very high is corroborated by the facts that a $P(Z = 0{\cdot}5)$-value of 1 mW./gm., for the coal under consideration corresponds to $T_1 \approx 4 \times 10^{-5}$ sec., and that Garif'yanov and Kozyrev[2] measured $T_1 = 12 \times 10^{-8}$ sec. for an anthracite.

I would also direct attention to the influence of ash content. In two cases measurements were made on samples of low and high ash contents (the latter samples are indicated by A in Fig. 1). It is seen that the presence of ash causes a rise of $P(Z = 0{\cdot}5)$. At the same time T_1 decreases, which suggests an increase in the exchange between the unpaired electrons and the surroundings. In both cases the samples of high ash-content proved to contain more free radicals than the practically ash-free samples, which seems to indicate that, at least in the two cases considered, the ash contains paramagnetic components.

Dispersion Energies in Porous Sorbents

De Boer and Custers[1], by an integration process, approximated to the energy of interaction by dispersion forces between a molecule and several types of cavity. On a plane surface containing N atoms of substrate per cm.^{3} the interaction energy is near to

$$E_1 = -\frac{\pi N A}{6} \times \frac{1}{r^3} \qquad (1)$$

if the interaction energy between an isolated sorbate molecule and the nearest atom of sorbent is given by $-A/r^6$. A is a constant given approximately by the London theory of dispersion forces[2]. Then, in turn, in a hemispherical pocket, at the bottom of a very long cylindrical capillary with a hemispherical end, and in an isolated spherical cavity, all of radius r and just large enough to contain the molecules, the energies of interaction are respectively $E_2 = 4E_1$, $E_3 = 6{\cdot}36E_1$ and $E_4 = 8E_1$.

This calculation indicates that very large maximum enhancements of sorption energies could be expected in suitable capillaries. For two plane parallel surfaces r apart, $E_5 = 2E_1$. Thus, in slit-shaped cavities such as could occur with graphite, the ratio between initial and limiting heats of sorption may approach two. Such a ratio has indeed been observed, and the above explanation of it has been suggested[3]. However, with highly porous sorbents one may easily exaggerate the enhancement of dispersion forces due to environment, and I wish to subject the idea of this enhancement to a more critical examination.

In the first instance the perfect fit of a sorbate molecule into the pocket (energy $= E_2$), channel (energy = E_3) or cavity (energy = E_4) will not be encountered in practice. In the nearly spherical cavities in β-quinol, it is true that the free diameter is ∼3·9 A., accommodating one argon atom of diameter 3·83 A. neatly[4]. (By 'free' is meant not occupied even by the peripheries of the framework-forming atoms of the lattice.) However, in water clathrates of Type 1, the free diameter is 5·9 A. or 5·2 A.[5] (a 'loose' fit for one argon atom); in chabazite it is ∼7·3 A.[6] (three argon atoms just accommodated); in Linde sieve *A* it is ∼11·8–11·4. A.[6,7] (filled by thirteen argon atoms); while in faujasite it is ∼12–13 A.[6,8,9], filled by eighteen argon atoms. (In the last three sorbents the cavities are also linked by narrower windows into a network of channels, the diameter of which thus varies periodically along their lengths.) Also, and perhaps even more important for such intracrystalline sorptions, a molecule in a cavity is not interacting with a dense atomic distribution outside the cavity, but with a honeycomb-like structure having a rather small density of atoms per $cm.^3$ of sorbent.

One way to demonstrate this last situation is to give per $cm.^3$ of sorbent host-lattice the number *N* of the atoms of the host lattice. This is done in Table 1, which also gives isosteric heats of sorption at zero coverage and for finite coverage. In column 2 it is seen that *N* for the important oxygen and carbon atoms of the honeycomb-like sorbents (including β-quinol and the β-ice water lattice in gas hydrates) is only about a third to a quarter of its value in compact solid-sorbents such as rutile or graphite. Thus the value of *N* in equation 1 is an important factor in *reducing* the enhancement of dispersion forces in these intracrystalline environments. Indeed, E_4 could be reduced by this factor from $\sim 8E_1$ to $\sim 2E_1$. If now we compare the situation for argon inside carbon-rich β-quinol with that for argon adsorbed on a non-porous carbon such as the 'Spheron' or 'Graphon' of Table 1 we find ratios of sorption heats E_4/E_1 a little less than two, and very far from the maximum value of eight suggested by de Boer and Custers's treatment. This is despite the nearly perfect fit of argon into the β-quinol cavities. Moreover, when we compare the initial isosteric sorption heats of argon for finely porous 'Saran' carbons with those of non-porous 'Graphon' or 'Spheron' an enhancement is seen for the porous sorbents but only of ∼1·5 fold, again much less than the optimum value of eight.

Coming now to the porous oxygen-rich sorbents, chabazite and faujasite, and the dense rutile, it is seen from Table 1 that isosteric heats for argon for larger amounts sorbed are about the same on all three sorbents (polarization energy contributes to initial heats[12], especially for the calcium-rich chabazite crystals, so that the initial heats do not measure only dispersion energies). Evidently, then, the intracrystalline environment of argon in chabazite and faujasite is largely offset by the greater density of oxygen atoms for non-porous rutile, even though the argon is present only on external surfaces of rutile crystals.

Flame Ionization Detector for Gas Chromatography

A NUMBER of gas chromatography detectors depending on ionization of the eluted gases have recently been reported[1]. Ionization has been effected either by β-rays from a radioactive source, or by a low-pressure glow discharge, or by electrons emitted in an ionization gauge.

A sensitive detector has been developed which depends on the ionization of the effluent in a hydrogen flame. A schematic diagram of the detector is shown in Fig. 1. The gases from the column in a suitable inert carrier are mixed with hydrogen, and burned in air at the tip of the glass jet. If hydrogen is used as the carrier gas, mixing is naturally unnecessary. The platinum electrodes are arranged to be in contact with the flame, the spacing being not very critical.

The electrical circuit used, Fig. 2, consists of a balanced cathode-follower impedance transformer. With a 0–1 m.amp. meter or recorder connected to the output terminals, full-scale deflexion was

produced with an injected sample of 1 µl., with a signal-to-noise ratio of better than 1,000 to 1, and no observable base-line drift over a wide range of operating conditions. The ultimate sensitivity of this detector has not yet been established.

A typical chromatogram using this detector is shown in Fig. 3. The electrical output appears to depend linearly on the sample size and was tested up to 10 µl., the reproducibility being at all times limited only by injection precision.

As the detector is constructed entirely of glass and metal, it is well suited to the detection of fractions from high-temperature columns.

A more detailed description of the detector will be published shortly.

Electric Double Hysteresis in $(K_x\ Na_{1-x})NbO_3$ Single Crystals

Sodium niobate forms solid solutions of perovskite type structure with the niobates of potassium[1], cadmium[2] and lead[3]. At quite low concentrations of the latter in these compositions the room temperature orthorhombic antiferroelectric structure of pure sodium niobate ($NaNbO_3$) gives place to an orthorhombic ferroelectric form. The phase-change between these two structures has not, however, been observed in any of these systems. In the ceramic specimens which have been examined, the ferroelectric properties increase gradually over a range of compositions. Pure sodium niobate single crystals, on the other hand, show double hysteresis loops at high fields[4] suggesting a discontinuous change to a ferroelectric form.

Using the techniques previously developed for sodium niobate, I have now extended the single-crystal measurements to the system $(K_x\ Na_{1-x})NbO_3$, and find the following properties. The phase diagram, determined optically on a hot-stage polarizing microscope, is shown in Fig. 1. The behaviour of specimens in both regions *a* and *b* is characteristic of orthorhombic crystals of cubic habit, with twinned regions showing parallel and symmetric extinction, and there is no qualitative optical distinction between them. The refractive indices and birefringence are, however, different in *a* and *b*, so that the phase change in a single crystal may be readily distinguished. The lines 1, 2, represent extreme cases of the survival of phase *b* in *a*, and vice versa, and it is probable that the two phases co-exist over the whole region *ab*.

Crystals of pure sodium niobate show electric double hysteresis for fields greater than 90 kV./cm. perpendicular to the orthorhombic *c*-axis. With increasing potassium niobate content, the field required to initiate hysteresis in the mixed crystals is continuously reduced, and the halves of the double loop commence to overlap. As the composition approaches the boundary 1 on Fig. 1 (in the region of 0·6 mole per cent potassium niobate), the electrical properties become more complex and markedly

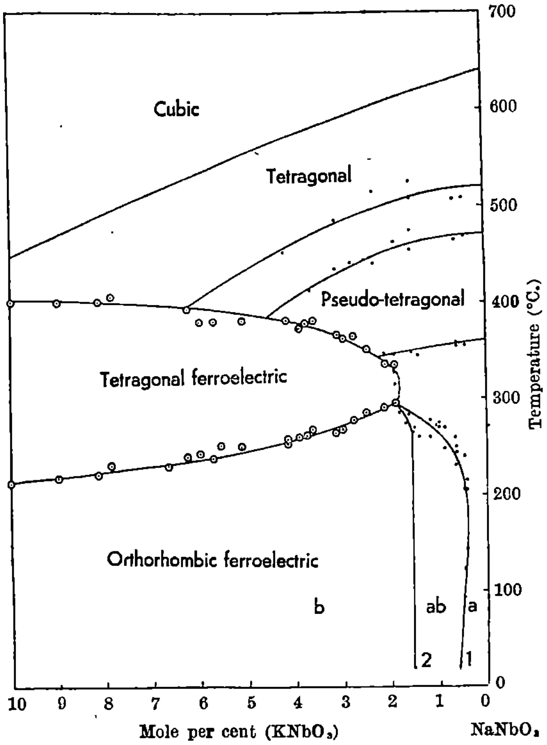

Fig. 1. Phase diagram for mixed $(K_xNa_{1-x})NbO_3$ crystals

dependent on pre-treatment. In virgin crystals, *PαE* is approximately linear up to a critical field-strength of the order of 20 kV./cm. at 50 c./s. Above this value, the initial cycles of the field produce double hysteresis loops, but subsequent cycling rapidly produces a ferroelectric loop (Fig. 2). Normal hysteresis persists below the previous critical field strength, and the performance of the virgin crystal is only regained after a sufficient period free from external fields. The time taken to recover varies widely between different specimens, but generally appears to increase as the composition approaches the phase boundary. With compositions containing more than 0·6 mole per cent potassium niobate, the mixed crystals give ferroelectric hysteresis loops.

These measurements confirm the discontinuous nature of the phase transition between antiferroelectric and ferroelectric orthorhombic structures in the $(K_x Na_{1-x})NbO_3$ system of solid solutions. The two structures, however, coexist over a considerably wider range of temperature than has been evident in any previously observed phase-change in a perovskite material.

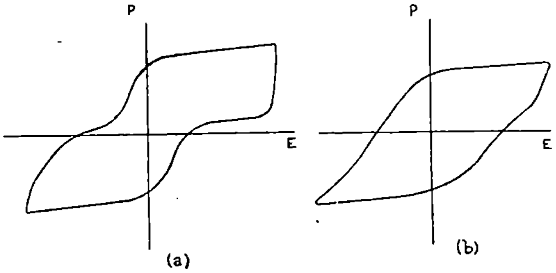

Fig. 2. Electric hysteresis in a single crystal of composition $(K_{0\cdot 0005}\ Na_{0\cdot 995})NbO_3$. (*a*) Initial application of 42 kV./cm. at 50 c./s. perpendicular to the orthorhombic *c*-axis; (*b*) 40 kV./cm. at 50 c./s. 1 hr. after cycling with 50 kV./cm. at 50 c./s.

There are a number of possible explanations for the absence of any discontinuity in the electrical properties of the equivalent ceramic materials. For compositions close to $NaNbO_3$ the single-crystal loops show that the field required to change the spontaneous polarization is high. There is also some evidence that the 'coercivity' increases with decreasing specimen thickness; thus with the distribution of orientations, and small crystallite size in the ceramics, it may not be possible to produce polarization re-orientation until the composition is markedly ferroelectric. It is probable also that there are larger composition inhomogeneities in the ceramics than in the single crystals, again tending to smear out the transition.

The very close proximity of the ferroelectric *b* phase to the pure sodium niobate makes it appear likely that similar phase-changes exist in the cadmium and lead systems. It is doubtful, however, whether the phase boundaries will be detected without a systematic investigation of single crystals of these materials.

A more complete account of this work, and the correlation with the thermodynamic treatment[5] of the properties of the solid solution sequence will be published elsewhere.

Germanium and Gallium in Sea-Water

Germanium

No quantitative data have so far been published for the concentration of germanium in sea-water. The first observation of germanium in a specimen of marine origin was due to Cornec[1], who detected it spectrographically in the ash of *Laminaria* sp. Noddack and Noddack[2] found the element in nine widely differing marine organisms in amounts ranging from 0·07 to 2·2 p.p.m. They were unable to detect it in sea-water, and concluded that its concentration must be less than 0·1 μgm./l. Bardet *et al.*[3] attempted to co-precipitate a number of trace elements from 60-l. samples of sea-water from Roscoff (Brittany) using seven different carriers; spectrographic examination of the precipitates revealed the presence of germanium in three cases.

Buljan[4] and Ishibashi and Shigematsu[5] have attempted to predict the abundances of the elements in sea-water, and have arrived at the values of 73 and 0·2 μgm./l. respectively for the concentration of germanium. The former figure is obviously much too high, since it would give a silicon : germanium ratio in sea-water of about 20 : 1 as compared with a ratio of about 140,000 : 1 in the lithosphere (Riley, J. P., and Burton, J. D., unpublished work).

In order to get some quantitative information on the concentration of germanium in sea-water, 5-l. samples of sea-water were treated with ferric alum solution. The resultant precipitate of ferric hydroxide, which carried down more than 97 per cent of the germanium present in the sea-water, was dissolved in concentrated hydrochloric acid. Germanium was extracted from the acid solution with carbon tetrachloride, back-extracted with water and determined spectrophotometrically with phenylfluorone.

Surface samples of water from the Irish Sea (2), the English Channel (4) and the North Atlantic (2) were found to contain 0·06 ± 0·01 µgm. of germanium/kgm. (0·82 ± 0·13 µgm.-atom/ton). Samples taken at depths of 240–270 m. and 3,660–3,900 m. at lat. 47° 47′ N., long. 9° 18′ W., contained 0·06 and 0·07 µgm./kgm. (0·82 and 0·96 µgm.-atom/ton) respectively. The average germanium concentration found is of the same order as that predicted by Ishibashi and Shigematsu[5]. Germanium is concentrated in sea-water, relative to the closely related element silicon, having a silicon : germanium ratio of about 17,000 : 1 (assuming a silicon concentration of 1,000 µgm. silicon/l., which is probably considerably higher than average); compared with a ratio of about 140,000 : 1 in the lithosphere. The concentration of the element in sea-water is much more constant than that of silicon, which varies[6] over the range 10–2,500 µgm./kgm. This constancy is probably attributable to the fact that, unlike silicon, it is not utilized appreciably by plankton.

Further work is in progress on the marine geochemistry of germanium.

Gallium

LITTLE is known of the occurrence of gallium in sea-water. Its presence was first detected by del Campo and Rodeja[1]. Bardet *et al.*[2] found it spectrographically, together with thirteen other trace elements, in water samples taken near Roscoff (Brittany). The only quantitative data so far published are due to Noddack and Noddack[3], who found 0·5 µgm. of gallium/l. in the water of Gullmars Fjord, Göteborg, Sweden; this analysis can scarcely be considered representative of ocean water, since the sample was taken from a fjord which is likely to be contaminated by drainage from the land. Ishibashi and Shigematsu[4] have predicted the abundance of gallium in sea-water to be 0·005 µgm./l.

The present communication records an attempt to obtain quantitative data on the occurrence of gallium in sea-water. The element was precipitated in 93 ± 5 per cent yield from 5-l. samples of filtered sea-water using ferric hydroxide as carrier. The ferric hydroxide precipitate was dissolved in hydrochloric acid, titanous chloride was added to reduce the iron to the ferrous state, and gallium was then extracted with di-*iso*-propyl ether. After evaporation of the ether, gallium was determined spectrophotometrically in the residue, using a modification[5] of the rhodamine *B* method of Onishi and Sandell[6].

Samples of the surface waters of the Irish Sea (4), the English Channel (1), and North Atlantic (2) contained 0·030 ± 0·007 µgm. gallium/kgm. (0·43 ± 0·10 µgm.-atom/ton). Two samples taken at depths of 240–270 m. and 3,660–3,900 m. at lat. 47° 47′ N., long. 9° 18′ W. contained 0·037 and 0·023 µgm. gallium/kgm. (0·53 and 0·33 µgm.-atom/ton) respectively. It is not considered that these variations are significant, since they are of the same order as the analytical error. The average gallium content of sea-water is thus about 0·03 µgm./kgm.—a value very much less than that found spectrographically by the Noddacks, but more in line with the relative abundance of the element in the lithosphere.

Further work on the occurrence of gallium in marine organisms and sediments is in progress.

'Sub-Grains' and Etch Figures in Lead

IN the course of a recent investigation into the ageing characteristics of lead–antimony alloys[1], microscopical examinations of a range of aged specimens were carried out and recrystallized areas were observed in a number of the specimens which had been strained prior to ageing. The specimens had been prepared by the normal metallographic techniques of grinding and polishing and had been etched in Worner and Worner's reagent[2] to disclose the extent of precipitation. In a number of the specimens the precipitated antimony was cleared from the surface by a brief immersion in concentrated nitric acid (s.g. 1·42) and subsequent examinations showed the recrystallized areas to be covered with networks of fine lines producing an appearance of sub-grains, similar to that due to polygonization, which had been absent from the specimens prior to the nitric acid treatment.

Specimens of unalloyed lead which were given the same etching treatment were found to show this structure over their entire surfaces even in cast material, and modifications in straining and annealing procedure did not produce changes in sub-grain dimensions. Repeatedly re-etching the same area of a single specimen did not develop the same configuration of sub-grains, and it was concluded that the network of lines did not result from the structure of the lead but was an effect produced primarily by the action of the nitric acid.

The effects of etching treatments in a range of concentrations of nitric acid on prepared specimens of annealed, unalloyed lead were then observed and it was seen that the 'sub-grain' dimensions increased with the degree of dilution of the nitric acid (see Figs. 1 *a* and *b*). At 20 per cent dilution a mottling of the surface had started to spread from the 'sub-grain' boundaries and at 30 per cent dilution the entire surface was mottled and etch figures had started to form within the 'sub-grains' (see Fig. 1 *c*). These etch figures continued to develop to the extent shown in Fig. 1 *d* by treatment in nitric acid diluted 40 per cent.

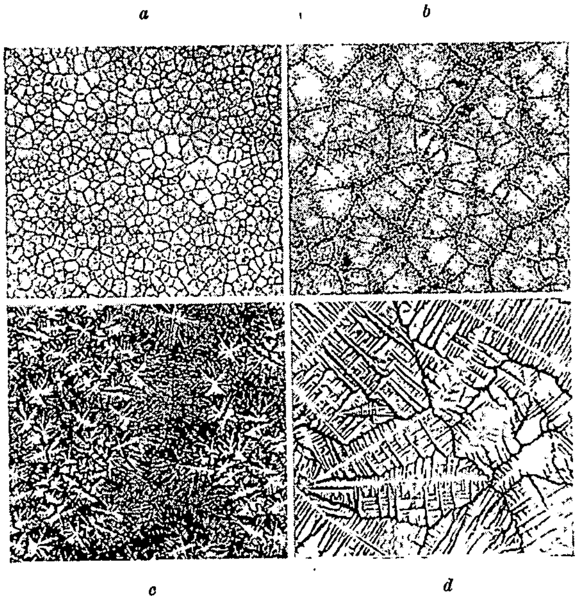

Fig. 1. *a*, Pure lead, treated in Worner and Worner's reagent and then in concentrated nitric acid, s.g. 1·42; *b*, as *a*, but finally treated in nitric acid, diluted 20 per cent; *c*, as *a*, but finally treated in nitric acid, diluted 30 per cent; *d*, as *a*, but finally treated in nitric acid, diluted 40 per cent. Anomalous Atmospheric Refraction at Sea

During the Atlantic crossing on Research Yacht *Princess Waimai* in 1954, to increase the accuracy of navigation astronomical sights were taken, as a rule, in series of observations: the noon sight series, extending usually for about an hour, with the Sun's culmination in its middle, 9 a.m. and 3 p.m. series, extending for about 20 min. Observations were taken about every minute. In all, 46 noon sight curves were obtained and 72 others, all in good weather conditions, within the tropics. The sextant used was a Henry Hughes instrument, with a recent class *A* National Physical Laboratory certificate. The height of the eye varied for different series of sights between 6 ft. and 10 ft.; estimated accuracy of observations within ±0·5 min. of arc.

Considering all the material, it appears that 24 per cent of sight points deviate by 2 min. of arc or more, and ½ per cent by 5 min. of arc or more, from interpolated curves.

Deviating points rarely appear at random, but rather in groups of three to five consecutive points, showing the same sign of deviation. But when a deviating group covers the culmination, there is often change of sign of deviation when the culmination is passed, that is, when the azimuth changes very quickly and the telescope sweeps over large stretches of the horizon between two consecutive sights. Groups of points deviating on either side of the curve are equally frequent. Morning sights show the lowest deviation frequency, namely, 15 per cent. There is little difference in frequency between noon and afternoon sights.

A plausible explanation of this phenomenon seems to be fluctuations of horizon height due to anomalous atmospheric refraction.

Some experiments have also been devoted to sextant optics. It was found that polarizing optics are superior to standard coloured glass 'shades', with which the sextant is normally equipped. Such optics often allow better horizon definition and also provide continuity in dimming incoming light. A 'Polaroid' disk, attached to one end of a sextant telescope so that it could be rotated, and another one, also with free rotation, in place of standard sun 'shades', was used. By rotation of the telescope 'Polaroid' one obtains the horizon contrast, and then the rotation of the sun 'Polaroid' provides the continuity in dimming the Sun. As any glare coming from the sea surface can be cut out completely by the telescope 'Polaroid', there is little need for additional horizon 'shades'; but, if desired, a third 'Polaroid', also with free rotation, can be attached in their place.

Effect of the Metallic Ion on the Infra-Red Spectra of Salts of Carboxylic Acids

A full analysis of the infra-red spectra of salts of carboxylic acids requires an interpretation of the effect of the metallic ion. Although a theoretical study of the formate ion has been published, a fundamental investigation of the perturbation caused by the presence of the metal ion has not yet been attempted[1]. Therefore, at present it is necessary to rely on empirical correlations.

The strong absorption bands attributed to the unsymmetrical (ω_2 at 6·2–6·6μ) and symmetrical (ω_1 at 7·1–7·7μ) vibrations of the carboxylate ion (COO^-) have been the most thoroughly investigated[2].

Recently, Kagarise[3] reported that for mono- and di-valent metals there are linear relationships between electronegativity and wave number of the ω_2 band for eight metallic phenyl stearates. Theimer and Theimer[4] have claimed that there is a relationship between the ionic radius of the metal and the Raman ω_1 band for the salts of five fatty acids.

The relationships claimed by Kagarise must not be regarded as general. Preliminary results on eight

Table 1

Metal	Electro-negativity	Ionic charge	Radius (A.)	Wave-length of ω_2 band (μ)*
Li	1·0	+	0·78	6·348 (*S*); 6·442 (*M*)
Na	0·9	+	0·98	6·362 (*S*); 6·421 (*W*); 6·503 (*S*)
Mg	1·2	++	0·78	6·368–6·386 (*S*) broad band
K	0·8	+	1·33	6·415 (*S*)
Ca	1·0	++	1·06	6·362 (*S*); 6·510 (*S*)
Zn	*c*. 1·6	++	0·83	6·510 (*S*)
Ba	0·9	++	1·43	6·625 (*S*)
Pb	—	++	1·32	6·627 (*S*)

* The spectra were determined in 'Nujol' mulls with a Grubb Parsons double-beam infra-red spectrometer, with rock salt optics. Strength of band: *S*, strong; *M*, medium; *W*, weak.

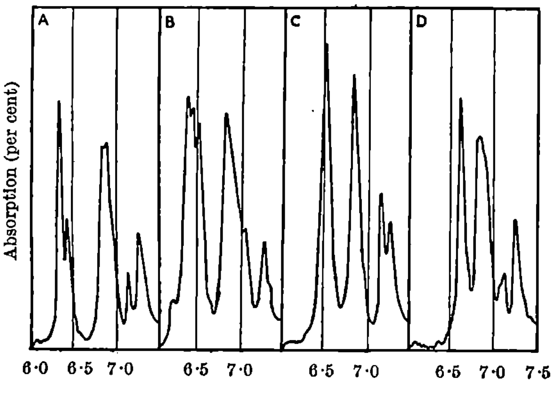

Fig. 1. Spectra of metal stearates (determined in 'Nujol' mulls). *A*, Lithium stearate; *B*, sodium stearate; *C*, zinc stearate; *D*, barium stearate

metallic stearates show that the effect of the metallic ion may be more complicated than a simple change in frequency of the ω_2 carboxylate band (see Table 1 and Fig. 1). The splitting of this band into a doublet (lithium and calcium) and a triplet (sodium) requires further investigation.

The influence of the metal ion may not be simply related to any one single factor. However, inspection of Table 1 shows that there is no relationship for these metallic stearates between the wave-length of the ω_2 band and either the electronegativity or the ionic radius of the metal.

For the eight metallic stearates investigated the dominant influence of the mass of the metal in determining the perturbation of the ω_2 carboxylate band is clearly illustrated in Fig. 2. However, because of the occurrence of doublets and triplets it is not possible to determine a single relationship between the wave-length of the ω_2 band and the mass of the metal ion.

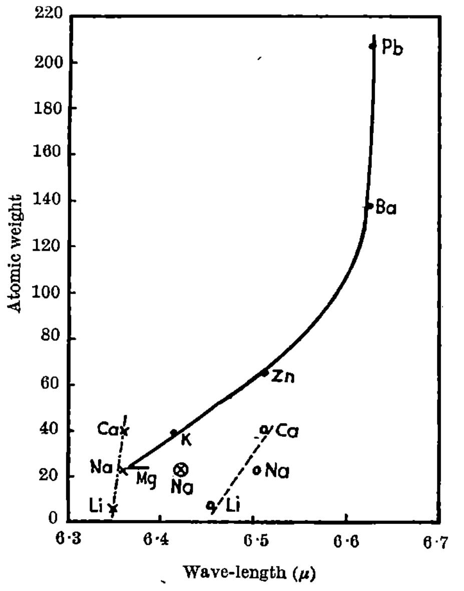

Fig. 2. Atomic weight versus wave-length of ω_2 carboxylate band for metallic stearates. ●, Single absorption band; × shorter wave-length of doublets; ○, longer wave-length of doublets; ⊗, intermediate weak peak (sodium stearate); —, broad band (magnesium stearate)

The dependence on mass noted here for metallic stearates is supported by the relationship between mass and frequency found in the spectra of carbonates[5] and metallic acetyl acetonates[6].

A New Class of Antibiotic Salts of Reduced Toxicity

We have recently reported[1] the preparation and acute toxicity of a number of salts of basic antibiotics with acid vitamins. However, the good results obtained with the pantothenates in the reduction of the neurotoxicity of streptomycin[2,3] have not been as marked in the prevention of nephrotoxicity and other side effects produced by neomycin[4] and viomycin[4,5]. This prompted us to prepare other types of salts of antibiotics.

It was Short[6] who first reported that methionine and S-methyl-L-cysteine reduced the nephrotoxicity of polymyxin A. Kimmerle and Gösswald[7] showed that N-acetylmethionine reduced the toxicity of streptomycin and briefly mentioned that the leucinate of the same antibiotic had no advantage over the sulphate. We record here the preparation of amino-acid salts of basic antibiotics that may prove of interest not only in the general reduction of toxicity but also in the detoxication of specific organs.

The dihydrostreptomycin salts were prepared by neutralization of concentrated aqueous solutions of the base with three moles of the amino-acid or by double decomposition between solutions of dihydrostreptomycin sulphate and of an equivalent quantity of the proper barium amino-salt. The salts were then obtained by freeze-drying the solutions or concentrating them under reduced pressure at room temperature, dissolving the syrup in methyl alcohol and precipitating with a ten-fold excess of acetone. The tri-salts are stable in the solid state. They are very soluble in water giving solutions slightly alkaline except when the amino-group is acylated. The following salts were prepared: Glycinate (Anal. Calc. for $C_{27}H_{56}N_{10}O_{18}$: C, 40·09; H, 6·98; N, 17·32; Found: C, 39·99; H, 7·14; N, 17·15); DL-leucinate (Anal. Calc. for $C_{39}H_{80}N_{10}O_{18}$; C, 47·94; H, 8·25; N, 14·34. Found: C, 47·78; H, 8·45; N, 14·09); L-glutamate (Anal. Calc. for $C_{36}H_{68}N_{10}O_{24}$: C, 42·18; H, 6·69; N, 13·67. Found: C, 42·40; H, 6·97; N, 13·40); L-methioninate (Anal. Calc. for $C_{36}H_{74}N_{10}O_{18}S_3$: C, 41·93; H, 7·23; N, 13·58. Found: C, 42·16; H, 7·61; N, 13·47); N-acetyl-DL-methioninate (Anal. Calc. for $C_{42}H_{80}N_{10}O_{21}S_3$: C, 43·58; H, 6·97; N, 12·10. Found: C, 43·42; H, 6·94; N, 11·80) and S-ethyl-L-cysteinate (Anal.

Table 1. Acute Intravenous Toxicity of Salts of Dihydrostreptomycin

Salt	Potency γ base/mgm.	LD50 mgm. base/20 gm.
Glycinate	721	3·38
DL-Leucinate	597	3·94
L-Glutamate	569	3·74
L-Methioninate	566	4·12
N-Acetyl-DL-methioninate	504	3·32
S-Ethyl-L-cysteinate	566	3·17
Sulphate	799	3·18
Ascorbate (ref. 1)	524	4·55
Pantothenate	470	3·80
Glucuronate	500	3·24

Calc. for $C_{36}H_{74}N_{10}O_{18}S_3$: C, 41·93; H, 7·23; N, 13·58. Found: C, 41·28; H, 7·58; N, 13·50).

The acute intravenous toxicities determined in white mice are shown in Table 1, which includes for comparison the sulphate, pantothenate, ascorbate and glucuronate (prepared by a method similar to U.S. Patent 2,583,534, December 31, 1949).

The acute toxicities are, in most cases, lower than those of the sulphate or glucuronate except the S-ethyl-L-cysteinate in which, however, the anion also has tuberculostatic activity[8]. The leucinate and the methioninate are being studied further. These are less toxic than the pantothenate, and only the ascorbate is less toxic than they.

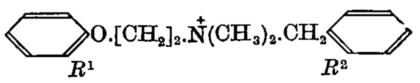
A New Series of Anthelmintics

We wish to report a new series of chemical compounds effective against nematodes parasitic in the gastro-intestinal tract of mammals. Certain of these compounds possess an unusually broad anthelmintic spectrum which includes appreciable activity against certain species causing infections of economic importance for which there is, at present, no satisfactory treatment.



(I)

These compounds (patent applications pending) have the general formula (I), where R^1 can be hydrogen, methyl or chlorine, while R^2 can be hydrogen, methyl, chlorine or fluorine. Lower activities are encountered when R^1 is a nitro-group, bromine or when R^2 is bromine. Numerous other variants are in course of examination.

The synthesis and initial biological assay of the series were carried out by two of us (F. C. C. and O. D. S.). *Nippostrongylus muris* was used as the test organism in this work. Afterwards, biological testing was extended to observe the effects of the more active compounds against trichostrongylid nematodes in sheep, *Uncinaria stenocephala* in dogs (J. S. and D. A. R.) and *Ancylostoma caninum* in dogs and cats (R. B. B.) as well as other species of nematodes cultured in small laboratory animals.

Certain members of the series possess anthelmintic activity against a wide range of species. It is of particular interest that these compounds appear to be more effective against the mucosa-dwelling species of parasitic nematode than against those living more freely in the lumen. Thus, considerable activity has been demonstrated against *N. muris* in the rat; *Nematospiroides dubius* in the mouse; *Nematodirus* sp., *Haemonchus contortus*, *Trichostrongylus axei*, *Cooperia curticei* and *Ostertagia* spp. in the sheep; *A. caninum* in the dog and cat. Lower activity has been demonstrated against *U. stenocephala*, *Aspiculuris tetraptera*, *Syphacea obvelata*, *Toxocara canis*, *T. cati*, *in vivo* and against *Ascaris lumbricoides* (from the pig), *in vitro*. The full range of activity has yet to be established. Field trials are in progress, and clinical trials are to be undertaken.

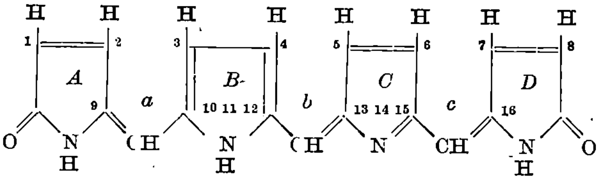
The IX-α Structure of the Common Bile Pigments

It is generally accepted that all the naturally occurring 'tetrapyrrolic' bile pigments must be of a IX-α structure, that is, that they are derived from the biliverdin which is produced biologically by rupture of the α-methene bridge carbon atom of protoporphyrin IX. Therefore, all bile pigments prepared from biological material should possess a 1,3,6,7-tetramethyl-4,5-dicarboxyethyl-2,8-divinyl (or diethyl), open-chain, 'tetrapyrrolic' structure (using the system of numbering shown in formula (I). Although some of the bile pigments have been synthesized by methods which exclude the formation of isomers other than IX-α, there is, at present, no analytical evidence of the absence of such isomers in the pigments obtained from biological sources. The presence of such isomers would be expected if biological fission of the protoporphyrin molecule did not occur exclusively at the α-methene linkage. Since stercobilin (and therefore also the less-hydrogenated bile pigments) is known to be produced by at least two distinct physiological mechanisms[1], such a possibility is not entirely speculative. The method of identification of pyrrole carboxylic acids described by one of us and used in investigations of the porphyrins[2] has now been applied to a study of the order of the β-side-chains of the bile pigments. In the bile pigments one α-position of each end ring bears an oxygen atom (usually formulated in a hydroxyl group[3]) instead of a carbon atom. It is therefore impossible for these rings, on degradation, to provide the αα′-pyrroledicarboxylic acids given under similar conditions by the corresponding porphyrins; any such acids can only originate from the middle rings of the pigment molecule.

The 'hydroxypyrroles' in general, and particularly those used in the syntheses of the bile pigments, are in fact pyrrolenones[4], and it is therefore probable that the bile pigments are also lactam compounds. The present systems of nomenclature[5] make no provision for this fact and do not allow easy derivation of the structures of the bile pigments. In this communication we have named the bile pigments as derivatives of the fully unsaturated structure I, to which we give the trivial name 'bilenone'.



(I)

The bile pigments are derived from I by appropriate substitution at positions 1–8 and by suitable reduction of any of the carbon–carbon double bonds shown with the exception of those in the two middle rings *B* and *C*. Rings *B* and *C*, together with the linking methene group, *b*, are assumed to constitute a resonating dipyrrylmethene unit; reduction of this by means of two atoms of hydrogen produces a dipyrrylmethane structure in which rings *B* and *C* are truly pyrrolic. The systematic names which result from the use of this system of nomenclature have been used in Table 1.

Table 1

Compounds oxidized	Acids obtained II	III	IV
Bilirubin 1,3,6,7-tetramethyl-4,5-dicarboxyethyl-2,8-divinyl-(*b*-13)-dihydrobilenone	++	–	–
Mesobilirubin 1,3,6,7-tetramethyl-4,5-dicarboxyethyl-2,8-diethyl-(*b*-13)-dihydrobilenone	++	–	–
Biliverdin 1,3,6,7-tetramethyl-4,5-dicarboxyethyl-2,8-divinyl-bilenone	++	–	–
Mesobiliviolin* 1,3,6,7-tetramethyl-4,5-dicarboxyethyl-2,8-diethyl-(*c*-16) dihydrobilenone	++	–	–
d-Urobilin † (ref. 7) 1,3,6,7-tetramethyl-4,5-dicarboxyethyl-2 (or 8)-ethyl-8-(or 2)-vinyl-(9-*a*),(*c*-16)-tetrahydrobilenone	+	—	–
Stercobilin 1,3,6,7-tetramethyl-4,5-dicarboxyethyl-2,8-diethyl-(1-2),(9-*a*),(*c*-16),(7-8)-octahydrobilenone	–	–	–
Glaucobilin 1,3,6,7-tetramethyl-4,5-dicarboxyethyl-2,8-diethyl-bilenone	++	–	–
Stercobilinogen 1,3,6,7-tetramethyl-4,5-dicarboxyethyl-2,8-diethyl-(1-2),(9-*a*),(*b*-13),(*c*-16),(7-8)-decahydrobilenone	–	–	–
Mesobilirubinogen 1,3,6,7-tetramethyl-4,5-dicarboxyethyl-2,8-diethyl-(9-*a*),(*b*-13),(*c*-16)hexahydrobilenone	+	–	–
Glaucobilin-XIII-*α* 1,3,6,8-tetramethyl-4,5-dicarboxyethyl-2,7-diethyl-bilenone	++	–	–
2,4-dimethyl-3-carboxyethylpyrrole-5-carboxylic acid	–	–	–

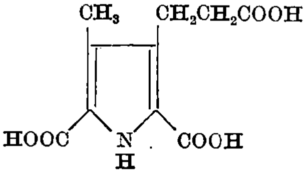
* Probably a mixture of mesobilirhodin and mesobiliviolin

† The positions of the ethyl- and vinyl-groups are not yet known with certainty.

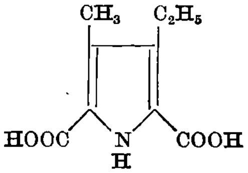
About 30 mgm. of each of the bile pigments mentioned in Table 1 were oxidized with alkaline potassium permanganate and the products were identified by chromatographic comparison with authentic 4-methyl-3-carboxyethylpyrrole-2,5-dicarboxylic acid (II), 4-methyl-3-ethylpyrrole-2,5-dicarboxylic acid (III) and 4-methylpyrrole-2,3,5-tricarboxylic acid (IV). With the exceptions of stercobilin and stercobilinogen all the pigments examined gave the acid (II) on oxidation; the same acid was obtained from the glaucobilin produced from stercobilin by treatment with sulphuric acid and from synthetic glaucobilin. The acids III and IV, which would be expected to arise from bile pigments derived from protoporphyrin on fission at the β-, γ- or δ-linkages, could not be detected in the products of oxidation of any of the pure bile pigments or of the mother liquors from the isolation of *d*-urobilin. The yields of the acid II indicated in Table 1, are those obtained from equivalent quantities of pigment and were assessed by inspection of the size of the chromatogram spots. The results permit the following conclusions to be drawn:

(*a*) The common bile pigments, including bilirubin, *d*-urobilin and stercobilin (after conversion to glaucobilin) are wholly IX-α in structure.

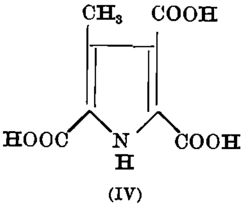
(*b*) Oxidation of stercobilin and stercobilinogen proceeds without the formation of pyrrolic acids. This is an interesting indication that the two end-rings *A* and *D* are completely hydrogenated and of a stable aliphatic nature. In agreement it was found that the monopyrrole V, which resembles the latest structure postulated for stercobilin[6] in having a saturated α-substituent, furnishes no trace of acid II under the conditions of oxidation used for the bile pigments. In contrast, the oxidation of mesobilirubinogen and *d*-urobilin (in which the groups attached to the dipyrrylmethene unit have an element of unsaturation) produced acid II. The



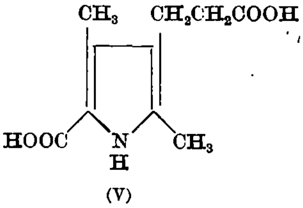
(II)



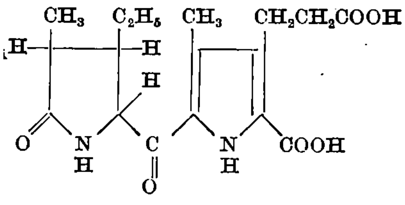
(III)



(IV)



(V)



(VI)

product arising from stercobilin appears to be a water-soluble acid which forms an optically active, 2,4-dinitrophenylhydrazone. It is possible that stercobilin undergoes fission at the *b*·12 or *b*-13 bond with formation of a product of the type VI. A study of the nature of this product is being undertaken.

One of us (R. A. N.) is indebted to the National Research Council (Rome) for financial support.

A Ribonucleoprotein from Amphibian Gastrulæ

Disaggregation of amphibian embryos by agents which chelate calcium is succeeded by re-aggregation if the cells are returned to a medium containing calcium[1]. It is customary to consider that the removal of calcium from the environment of the cells is responsible for the loss of adhesion displayed in disaggregation. An attempt has been made to find out whether any organic material is removed from the embryos during disaggregation. Such organic material might lie on the cell surfaces or between the cells and assist in their adhesion, or it might be removed from within the cells during disaggregation. Batches of 250–260 late gastrulæ of *Xenopus laevis* were disaggregated in 0·001 *M* ethylene diamine tetraacetate at *p*H 8·03 in *tris*-hydrochloric acid buffer (0·001 *M* in *tris*) made up in calcium-free Holtfreter solution. The embryos were gently agitated on a rocker for 40 min. at 19–21° C., and at the end of this period the cells of the completely disaggregated embryos were allowed to settle. No evidence of cytolysis of the cells could be found. The supernatant was removed and centrifuged at 300–400 *g* for 10 min. A small number of intact cells, and a few yolk platelets probably of extracellular origin, formed the residue. The clear supernatant from this centrifugation was examined spectrophotometrically, and the absorption curve suggested the presence of nucleic acids. The preparation was frozen-dried.

Estimations of the total nitrogen by the Lubochinsky test, phosphorus as phosphate after digestion in concentrated sulphuric acid, ribose by the orcinol reaction, and α-amino nitrogen by the ninhydrin method were made. Deoxyribose and hexose sugars were absent. After hydrolysis in perchloric acid the material was run on a chromatogram using *iso*propanol/hydrochloric acid/water (170 : 41 : to 250 vol.) as the solvent. Adenine, guanine, cytosine and uracil were recognized from the R_F values and from the absorption curves of the eluates of the spots. The extinction values of the various bases suggest that the nucleic acid forms 25 per cent of the dry weight of the material. This value is in agreement with the results of the other tests, and with the 260/280 mμ absorption ratio for the untreated material, which all give 75 per cent of protein in the preparation. A sample of the material was hydrolysed in 6 *N* hydrochloric acid, and a chromatogram of this hydrolysate was run in phenol saturated with water. Qualitatively, arginine, histidine and tyrosine have been recognized from R_F values and from specific reactions; exact identifications of the remaining amino-acids have not yet been done.

Embryos of this stage disaggregate in calcium-free media at or above *p*H 9·8, forming a clear jelly between the cells in the process, and show a certain amount of cytolysis. On returning the cells to *p*H 6·8 in the absence of calcium, the jelly slowly dissolves; if the return to *p*H 6·8 is done in the presence of calcium, the jelly remains. At this lower *p*H the jelly is dissolved by trypsin and by ribonuclease. It is possible that the jelly is at least in part identical with the ribonucleic acid and protein described above, though there is undoubtedly some degree of contamination with cytolytic products. Since ethylene diamine tetraacetate removes the ribonucleic acid and protein components from the embryos without visible damage to the cells, the suggestion is that they are derived from the surface of the cells or from between them. This is supported by histochemical evidence for the presence of ribonucleoproteins on or between the cells from methyl-green pyronin and toluidine blue staining (cf. ref. 2). The constant proportion that existed between the ribonucleic acid and protein components from batch to batch favours the view that they exist as a ribonucleoprotein in the embryo. Until the matter has been further investigated, it is probably most convenient to refer to the material as a ribonucleoprotein. It may be connected in function with the adhesion of cells to one another and with the binding of calcium on the cell surface, which is important in adhesion[3]. This function of ribonucleic acid on the cell surface has been suggested for *Elodea*[4]. It is of interest that if the disaggregated cells are treated with trypsin or ribonuclease they fail to re-aggregate, which suggests that there is a ribonucleoprotein on the cell surface connected with adhesion. It might also be concerned with induction and be related to the substance described by Niu[5].

I thank Prof. C. H. Waddington for his interest and for providing facilities for the work in the Institute of Animal Genetics, Edinburgh, Prof. J. N. Davidson for his interest and advice, and the Department of Scientific and Industrial Research for a maintenance grant.

β-Glucuronidase, Lipase and Esterase in the Testis of the Cryptorchid Rat

ALTHOUGH considerable attention has been paid to lipase and esterase in the testis[1], comparatively little is known of β-glucuronidase in this organ. This communication is concerned with some relationships between testicular β-glucuronidase, lipase and esterase of the rat in artificial cryptorchidism.

Thirty-four albino rats of the Wistar stock bred in this laboratory were used and grouped as follows: normal control (13), unilateral cryptorchidism (9), bilateral cryptorchidism (12). Determinations of enzyme activity in tissue homogenates were made according to the method of Talalay *et al.*[2] for β-glucuronidase, of Nachlas *et al.*[3] for lipase and for esterase; the units used were the amount of enzyme which liberates 1 μgm. of phenolic substance in 1 hr. for β-glucuronidase and for lipase, and in 20 min. for esterase[4].

Table 1

	Normal control	Cryptorchidism		
		Unilateral		Bilateral cryptorchid testes
		Normally located testis	Cryptorchid testis	
No. of rats	13	9		12
Body-weight (gm.)	132±10*	136±6·8		160±8·9
Testicular weight (mgm.)	742±80	1,078±100	567±69	541±58
β-Glucuronidase activity†	146±14	222±44	722±242	1,333±136
Lipase activity†	12±1·6	29±4·2	52±3·8	34±4·2
Esterase activity†	7,341±126	7,284±447	9,179±502	9,178±639

* Mean ± standard error of the mean.
† Units per gm. of wet tissue.

In the testis of the cryptorchid rat four weeks after operation, the concentrations of all three enzymes showed an increase. The most striking change was seen in the β-glucuronidase level. The concentration of this enzyme in the testis increased nine-fold in the bilaterally cryptorchid rat and five-fold in the unilaterally operated animal. Lipase concentration, however, increased much more in the cryptorchid testis of the unilaterally cryptorchid animal than in the bilaterally operated animal. The increase in the concentration of esterase was slight and the same in both groups. It should also be noted that β-glucuronidase and lipase activities were significantly ($P < 0·05$) elevated in the normally located testis of the unilaterally cryptorchid animal. Results are shown in Table 1.

A full account of this work will appear elsewhere.

Inhibition of 5-Hydroxytryptophan Decarboxylase by Phenylalanine Metabolites

EVIDENCE has recently been presented which demonstrated a lowered level of circulating 5-hydroxytryptamine in patients with phenylketonuria[1]. The condition is associated with production of an excess of certain aromatic acid metabolites of phenylalanine, which it has been claimed inhibit dihydroxyphenylalanine decarboxylase[2]. It was suggested that this inhibitory effect was an explanation of the low plasma levels of adrenaline found in phenylketonuria. As 5-hydroxytryptamine is derived from 5-hydroxytryptophan by the action of 5-hydroxytryptophan decarboxylase[3] it was decided to examine the effects of these aromatic acids on this enzyme system also.

Table 1. INHIBITION OF 5-HYDROXYTRYPTOPHAN DECARBOXYLASE BY PHENYLALANINE METABOLITES

Additions	Conc. (μmoles/ 3 ml.)	μl.CO$_2$/ 40 min.	Inhibition (per cent)	Inhibition of dihydroxyphenylalanine decarboxylase* (per cent)
Control	—	75·7	—	—
Phenylpyruvic acid	100	15·7	79·3	100
	50	38·3	49·5	100
	10	74·2	2	77
Phenyl-lactic acid	100	36	52·5	100
	50	66	13	77
	10	71·2	6	50
Phenylacetic acid	100	12·5	83·5	50
	50	24·2	68	0
	10	—	—	0
L-Phenylalanine	100	65·7	13	0

Guinea pig kidneys were homogenized in ice-cold *M*/30 Sørensen's phosphate buffer *p*H 6·8. The homogenate was centrifuged in the cold for 5 min. and 2 ml. of the supernatant (equivalent to 2 gm. of original wet tissue) used in each Warburg flask. 25 μgm. of pyridoxal phosphate and the inhibitor, dissolved in phosphate buffer, was added. The volume was adjusted to 2·75 ml. with phosphate buffer. After gassing for 2 min. with nitrogen, the flasks were equilibrated at 37° for 10 min. and 0·25 ml. of DL-5-hydroxytryptophan (10 μmoles) added from the side-arm. Controls and blanks were also used. Carbon dioxide output was determined for 40 min.

* After Fellman (ref. 2). Dihydroxyphenylalanine (20 μmoles) as substrate.

Phenylacetic acid was found to be more active and phenylpyruvic and phenyl-lactic acids were less active as inhibitors of 5-hydroxytryptophan decarboxylase when compared with the results presented by Fellman[2] for dihydroxyphenylalanine decarboxylase, which is similar to but not identical with 5-hydroxytryptophan decarboxylase[3].

These results, although preliminary, suggest the possibility that such an inhibition, *in vivo*, might be responsible for the decreased production of 5-hydroxytryptamine observed in patients with phenylketonuria. As there is a large body of evidence to suggest that 5-hydroxytryptamine plays a part in normal brain function, inhibition of 5-hydroxytryptophan decarboxylase, present in some areas of the brain in high concentration[4], might thus contribute to the cause of the mental defect in this disease.

It is of interest to note that ingestion of phenylacetic acid in man is followed by transitory mental disturbance[5]. But before the inference can be drawn that this effect is due to inhibition of 5-hydroxytryptophan decarboxylase more work must be done on the mechanism of this inhibition, and the possible inhibitory action on other enzyme systems[6] must be studied.

We are grateful to Dr. L. I. Woolf for gifts of the aromatic acids used.

Role of Ferrous Iron in Enzymatic Transamination

Although the part played by metals in non-enzymatic transaminations is known, its role in the enzymatic reaction of this type is still to be proved. Aluminium, nickel, copper and iron are known to catalyse the non-enzymatic reaction between an amino-acid and pyridoxal, or a keto-acid and pyridoxamine. Recently, Fasella *et al.*[1] have isolated the intermediates involved. This preliminary communication reports the possibility of iron (in its reduced state) being involved in the enzymatic transamination.

The source of the enzyme was the fresh green beans of *Dolichos lablab*. From the residue after acetone extraction of the beans, aspartic–glutamic transaminase was purified by 'Dowex-2' (in chloride form), calcium phosphate gel and alumina $C\gamma$ treatment. Electrophoresis (on paper) showed that the enzyme moved as a single component (*p*H 9·0, glycine–sodium hydroxide buffer, 4 cm. in 4 hr., 440 V., 26° C.) indicating a high state of purity. This purified preparation was used in the present work.

Preliminary experiments showed that metals such as aluminium, nickel, copper, magnesium, manganese and cobalt had no appreciable effect on the activity of the enzyme. Ferrous sulphate produced an increase in its activity, whereas mercury (as mercurous chloride) completely inhibited it.

As shown in Table 1, dialysis against 8-oxyquinoline solution (0·005 *M*) for 17 hr. in the cold reduced the activity of the enzyme considerably, but it was completely restored by addition of about 5 μgm. of ferrous iron (as $FeSO_4.7\,H_2O$) to the reaction mixture. Also there was no non-enzymatic transamination either in the presence or the absence of ferrous iron. Ferric iron (as $Fe_2(SO_4)_3$) was not active. Addition of ferrous iron to the undialysed enzyme had no effect. Among the various iron binders studied it was noticed that addition of glutathione, versene (disodium salt), O-phenanthroline and α-α-dipyridyl inhibited the activity by 10–20 per cent. Cyanide completely destroyed the activity, whereas 8-oxyquinoline had no effect at all.

Table 1. Effect of Ferrous Iron on Aspartic–Glutamic Transaminase

Reaction carried out at 37° C. for half an hour under nitrogen. Activity estimated by the method of Tonhazy (ref. 3)

Additions	Pyruvate formed (μgm.) per mgm. protein
Enzyme (undialysed) + asp. + KG	1,120
Enzyme (undialysed) + asp. + KG + 5 μgm. Fe^{2+}	1,160
Enzyme (dialysed) + asp. + KG	400
Enzyme (dialysed) + asp. + KG + 5 μgm. Fe^{2+}	1,230
Enzyme (boiled) + asp. + KG	Nil
Enzyme (boiled) + asp. + KG + 5 μgm. Fe^{2+}	Nil
Asp. + KG	Nil
Asp. + KG + 5 μgm. Fe^{2+}	Nil

asp. = DL-aspartic acid. KG = α-ketoglutaric acid.

Thus there appears to be an indication, for the first time, that a metal is involved in enzymatic transamination. In this connexion it can be stated that Dr. Cohen reported the presence of a strong Fe band in one of the Merck preparations of pyridoxal phosphate which was found to be twice as active as pyridoxal phosphate from other sources[2]. No exogenous coenzyme was used in the present investigation. Further work is in progress to isolate the enzyme in a high state of purity, in order to find whether there is iron in the enzyme, and also its mode of action.

I wish to thank Dr. M. Srinivasan and Mr. Nagabhushanam for their helpful discussions, and Dr. V. Subrahmanyan, director of this Institute, for his interest in the present investigation. Thanks are also due to Glyco Products Inc., New York, for a gift of versene.

Effect of Testosterone and Orchidectomy on the Activity of the Melanocytes in the Skin

It is well known that there is an increased pigmentation of the skin in certain areas of the body in pregnancy. It has also been established that the occurrence of a malignant change in benign pigmented tumours or moles is rare before puberty in both sexes. Furthermore it is accepted that the growth of malignant melanomas and the formation of metastases is accelerated during pregnancy[1]. All these facts suggest that the activity of the melanocyte is under hormonal influence. Edwards, Hamilton, Duntley and Hubert[2] reported that the human male castrate has a reduced amount of melanin in the skin. Treatment of these men with testosterone usually increased the melanin content in all areas, although the response was of small degree. Kupperman[3], working on the male golden hamster, showed that testosterone increases the pigmentation of the skin, whereas castration causes a reduction in pigmentation. Wheeler *et al.*[4] found by macroscopical and microscopical observations that topical application of testosterone to the nipples and areolæ of immature castrated male guinea pigs produced no increased pigmentation. The present investigation was designed to investigate histochemically the effect of testosterone and orchidectomy on the activity of the melanocyte.

Eighteen male guinea pigs weighing about 400 gm. were used. The animals were divided into three groups, each consisting of three pure black and three red guinea pigs. Skin biopsies were taken from all the animals from the right ear, right side of the anterior abdominal wall in the hypochondriac region and from the sole of the right foot. In addition, the right areola, including the nipple, was excised. The first group of animals was orchidectomized, received no hormone treatment, and was left for four weeks. The second group of animals was also orchidectomized, and four weeks later a course of testosterone was commenced. The animals were given 2 mgm. of testosterone propionate (Organon) intramuscularly once daily for 5 days a week for a period of 4 weeks. The third group of animals was left intact and was given a 4-week course of testosterone injections identical with that received by the animals of the second group. The animals were killed by a blow on the back of the neck, and a further series of skin specimens was removed from areas adjacent to those taken previously, and the left areola, including the nipple, was excised.

Most of the sheets of skin were left intact after excess subcutaneous fat and the deeper part of the dermis had been excised under a dissecting microscope. A few of the specimens, however, were treated with trypsin to disengage the epidermis. The skin was then incubated with the dopa reagent after preliminary fixation. The greater part of each skin sheet was then mounted; the remainder was embedded in paraffin and sagittal sections were cut. The hormonal influence on the melanocytes was studied by assessing the number and size of the melanocytes and the amount and position of the melanin within the cells in the skin specimens removed before and after treatment. The number, length and complexity of the dendritic processes were also noted, and an attempt was made to assess the amount of free melanin present in the vicinity of the cells.

The results were as follows:

Skin of ear. Following orchidectomy, no definite changes were noted. In the orchidectomized animals which received testosterone, in 2 of the animals the size of the melanocytes became reduced. In 3 of the animals, which included the 2 with a reduction in cell size, the dendrites were increased in length. The amount of melanin in the basal layer of the epidermis was increased in all the animals, but it was impossible to determine whether this increase had occurred within the melanocytes or in the surrounding tissue. In the intact animals which received testosterone the number of melanocytes became reduced in three of the animals and it was seen that the length and complexity of the dendrites of these cells were reduced. Furthermore it was noted that the amount of free melanin in these animals was increased.

Skin of anterior abdominal wall. Orchidectomy increased the number of melanocytes in 5 of the animals. In 2 of these the size of the melanocytes become reduced and in one it was increased. It was also seen that in 3 of the animals the amount of free melanin had increased, but this could not be correlated with the melanocyte changes. In the orchidectomized animals which received testosterone no uniform change occurred. There was a slight tendency for the size of the melanocytes and the amount of intracellular melanin, and the length and complexity of the dendrites, to become reduced. In the intact animals which received testosterone, no definite changes were seen.

Skin of areola. In the orchidectomized animals the changes noted were inconsistent. In 2 of the animals, however, the number of melanocytes and the amount of free melanin increased. In another 2 animals the length and complexity of the dendrites increased. In the orchidectomized animals which received testosterone no uniform changes occurred. In the intact animals which received testosterone, in 3 of the animals the number of melanocytes became increased. In 4 animals the amount of free melanin was increased, but in one animal it was reduced.

Sole of foot. In all three groups of animals the amount of melanin in the basal layer of the epidermis showed a definite increase.

The above findings show that orchidectomy, orchidectomy followed by testosterone, or testosterone alone, are incapable of producing uniform changes in the melanocytes and in the intra- and extra-cellular melanin in the skin of the ear, anterior abdominal wall and areola. It is therefore concluded that the melanocytes in the skin of these regions are not directly influenced by the male sex hormone. The results in the skin of the sole of the foot are, however, constant, and indicate that any change in the amount of male sex hormone will produce an increase in melanogenic activity. This is of particular interest in view of the high incidence of malignant change in pigmented lesions of the sole of the foot in man.

Effect of some Nitrogen Mustard Derivatives on Growth of Rabbit's Hair

THE stimulating effect of ionizing radiations on the growth of rabbit's hair has been noted recently[1]. It may be of interest to record that similar effects have been found following the application of certain nitrogen mustard derivatives to rabbit skin.

In 1948, the preparation of mustard derivatives of desylamine, $C_6H_5COCH(NH_2)C_6H_5$, was undertaken for studies in cancer chemotherapy. Desyl chloride, $C_6H_5COCHClC_6H_5$, and the *p*-methoxy bromo compound, $CH_3OC_6H_4COCHBrC_6H_5$, were prepared by standard methods and allowed to react with diethanolamine. The resulting bases,

$$RC_6H_4COCH\{N[(CH_2)_2OH]_2\}C_6H_5$$

had the following properties: for $R = H$, m.p. = 136 – 137° C., N per cent found = 4·46, N per cent calc. = 4·68; for $R = CH_3O$, m.p. = 108 – 109° C., N per cent found = 4·40, N per cent calc. = 4·26. Cold chloroform solutions of these products were treated with thionyl chloride (in the case of the methoxy derivative, the reaction mixture exhibited a transient deep blue-green colour) and, after removal of chloroform, white substances were obtained.

These compounds, which were hygroscopic and seemed to be susceptible to decomposition, were stored *in vacuo*. Analyses were unsatisfactory, but indicated that the products probably consisted mainly of hydrochlorides of the mustard derivatives,

$$RC_6H_4COCH\{N[(CH_2)_2Cl]_2\}C_6H_5$$

No further chemical studies were made with the substances; but their ability to produce blisters on the shaved skin of rabbits was investigated.

On November 17, 1948, a drop of a chloroform solution of the desyl mustard derivative ($R = H$; ~20 mgm.) was placed in the middle of a shaved area on the belly of a Dutch rabbit. The skin reddened at the site of application, and, 3 days later, a yellow area of thickened skin (blister) had formed at this site. On November 23, a thick keratinous layer was observed along the line of application of the mustard solution and by November 29 the keratin had sloughed off leaving a mark resembling a knife incision. On December 9, it was observed that hair about 1 cm. in length had grown on this mark, but the surrounding shaved area remained free from hair. On December 16, hair on the 'wound' site had grown to normal length and by February 21, 1949, a thick tuft of hair was growing on the site of application of the mustard while the rest of the shaved area remained hairless. On this day, fur was shaved from a fresh area of the experimental animal and a control animal was shaved on the belly. By March 3, 1949, there was a light growth of hair on the shaved area of the control animal and the site was completely covered with hair on March 10. At this time the recently shaved area on the mustard-treated rabbit showed no growth of hair.

Other rabbits were shaved on both flanks and one flank of each was treated with desyl or methoxy-desyl mustard on December 11, 1948. On February 28, 1949, growth of hair was observed on the painted site but scarcely any on the surrounding shaved area or on the control shaved flank.

Experiments with di-2-chloroethyl sulphide and di-2-chloroethylamine led to early death of the treated rabbits, so it remains uncertain whether these substances have the same action as the desyl mustards. It should be of interest to determine whether the observed effects can be obtained with other radiomimetic agents or carcinogenic substances.

The work described here was carried out with the aid of a grant from the British Empire Cancer Campaign. I am at present in receipt of a James Morrison Research Fellowship.

Effects of Gibberellic Acid on Soil Micro-organisms

GIBBERELLIC acid, a metabolic product of the fungus, *Gibberella fujikuroi*, has shown marked effects on plant growth, stimulating stem and leaf elongation. British investigators[1] have studied its influence on a number of bacteria and moulds and have briefly stated they were unable to detect any effect, either inhibitory or stimulatory. Although there is indirect evidence that gibberellic acid is rapidly decomposed in the soil[1], there have been no reports concerning action of the acid on soil micro-organisms and their activities. The following preliminary experiments were carried out to determine if gibberellic acid had any effect on terminal respiration of the soil microbial population in conventional Warburg runs.

5-gm. portions of air-dry sandy loam soil passing a 10-mesh sieve were placed in Warburg vessels[2]. The soil had a water-holding capacity of 37 per cent; 0·80 per cent total carbon and 0·06 per cent total nitrogen were present. Gibberellic acid, dissolved in a drop of ethanol, was added to duplicate flasks of the soil to give concentrations of 0, 1, 3, 5, 50 and 100 p.p.m. Glucose treatments at 2,000 p.p.m. carbon and ethanol controls in duplicate were included. In addition to the soil (vol., 2·5 ml.), each flask contained 0·5 ml. substrate and 0·2 ml. 20 per cent potassium hydroxide. Runs were made for 15 hr. at 29·8° C. and all values were corrected. The $Q_{O_2}N$ values were considerably increased by the ethanol. No significant increases were given by gibberellic acid; in some instances it gave slight decreases.

At the close of the respiration experiment, soil from the Warburg flasks was removed, appropriately diluted, and plated in quadruplicate for microbial counts and incubated at 28° C. Sodium albuminate agar was used as the medium for bacteria and *Streptomyces*, and peptone–glucose agar acidified to pH 3·9 was used for soil fungi. Plates were counted as soon as colonies could be well differentiated. Results were analysed statistically. The F values for treatments and interactions were significant at the 1 per cent level. The results disclosed that gibberellic acid in comparison with ethanol controls apparently induced some stimulations and some inhibitions not consistent with the rates of application. An explanation of these variations cannot be given from present information.

The most significant observation was that with the ethanolic gibberellic acid treatment at 50 p.p.m. + glucose, and ethanolic gibberellic acid at 100 p.p.m. + glucose, numerous colonies of *Azotobacter chroococcum* (as determined by cultural and microscopic examination), a non-symbiotic nitrogen-fixing bacterium, occurred on all replicate sodium albuminate agar plates. No such colonies were found on dilution plates from any of the soil treatments which did not include gibberellic acid. It is evident, however, that *Azotobacter*, in lesser numbers, must have been present in the original soil. This was confirmed by observation of typical *Azotobacter* colonies that developed on plaques of soil–starch paste. Therefore, in another experiment, which confirmed the first Warburg results, soil from the flasks was air-dried, sieved and tested for *Azotobacter*, using the nitrogen-free agar plate method[3]. After five days, *Azotobacter* were found to be numerous in all samples, but appeared most abundant with ethanolic gibberellic acid at 50 p.p.m. + glucose (Table 1).

Table 1. *Azotobacter* COLONIES FROM SOILS AFTER 15-HR. RESPIRATION IN WARBURG FLASKS

Treatment	Colonies per gm. soil*
Soil + gibberellic acid, 1 p.p.m.	2,200
Soil + gibberellic acid, 3 p.p.m.	3,200
Soil + gibberellic acid, 5 p.p.m.	2,600
Soil + gibberellic acid, 25 p.p.m. + glucose at 2,000 p.p.m. C.	2,400
Soil + gibberellic acid, 50 p.p.m. + glucose at 2,000 p.p.m. C.	3,400
Soil + glucose at 2,000 p.p.m. C.	2,000
Soil + ethanol, 14 p.p.m.	2,400
Soil only	2,000

* Average of duplicates

Further studies are in progress to determine if 'Gibrel', a water-soluble potassium salt of gibberellic acid, has a significant effect on nitrogen fixation by *Azotobacter*.

The gibberellic acid was kindly supplied by Dr. L. T. Blaney of the Horticulture Department. It was originally obtained from Dr. P. W. Brian of Imperial Chemical Industries, Ltd., England. The 'Gibrel' was supplied by Merck and Co., Inc., New Jersey.

Enzymes in the Ileal Juice of the Horse

So far as can be ascertained there is no information about the enzymes secreted by the horse's small intestine. Since a pony with a Thiry–Vella loop in the middle of the ileum was available[1] the opportunity was taken to determine whether the enzymes present in man and dogs were present in the horse. The juice was obtained by gently rubbing the mucosa with a rubber catheter. Juice thus obtained was, on occasion, slightly contaminated with blood. However, the enzymic activity of such samples did not differ from the uncontaminated.

Ileal juice is a watery fluid with a yellow tinge and sometimes contained mucus. The pH was 7·8–8·5. Enzymic activity was measured on the supernatant fluid from juice centrifuged at 3,000 r.p.m. for 5 min.

Amylase, lactase, maltase, and sucrase activity was detected by Lagerlof's[2] method, lipase activity by Cherry and Crandall's[3] method, peptidase by Cajori's[4] technique using a peptone substrate and protease by Lagerlof's[5] method with casein as substrate. Enterokinase activity was detected by using the protease method after adding 2 ml. of 0·01 per cent trypsinogen (Worthington Biochemical Corporation) to 6 ml. incubating mixture and using controls without trypsinogen and also, with boiled juice. This method showed marked enterokinase activity in the ileal juice of freshly killed rats and guinea pigs. The experimental findings are shown in Table 1; the dilution of juice was the highest at which activity could be detected by the methods used.

Table 1. Enzymes in Horse Ileal Juice

Enzyme	No. of observations	Activity present	Dilution of juice
Amylase	18	14	1 : 1,000
Sucrase	14	12	1 : 20
Lactase	19	17	1 : 1,000
Maltase	19	16	1 : 1,000
Lipase	4	0	Undiluted
Lipase	6	0	1 : 5
Protease	16	15	1 : 10
Peptidase	14	14	1 : 10
Enterokinase	7	1	Undiluted

It was interesting to compare the results of these experiments with those of Doller and Porter[6], who studied the enzymes of the calf's digestive tract. They found no sucrase activity in the calf's ileum and that the lactase activity decreased with age.

The absence from the horse juice of lipase activity was noteworthy, although Reale[7] has stated that lipase was absent from fresh ileal juice in man but increased with cellular autolysis, and Roger and Binet[8] suggested that bile increased lipolytic activity by destroying cells. However, in our experiments both centrifuged juice, macerated mucus and cellular debris were free from lipolytic activity. In control experiments the method employed showed marked lipolytic activity in ileal juice of rats and guinea pigs.

The absence of enterokinase activity could be explained by the Thiry–Vella loop being six years old, as Foa[9] showed the enzyme to disappear from fistulæ of dogs within six months of operation, and Sawitsch[10] found the enzyme to disappear from fistulæ deprived of pancreatic juice.

Effect of Electrolytes on the Uptake by Bacteria of Labelled Glutamate

In a recent paper, Krebs, Whittam and Hems[1] reported an accelerating effect of potassium salts on the rate of oxidation of various substrates by *Alcaligenes faecalis*. All the potassium salts tested were equally active. The ionic composition of the medium was found to affect respiration also in *Escherichia coli* (strain *B*), and *Pasteurella tularensis* (strain $S + D$)[2]. The effect of the anion was also apparent with these two micro-organisms. For the maximal rate of oxidation of glutamate and glucose by *P. tularensis* the halogen salts of potassium and rubidium were found to be required; in the case of *E. coli* potassium chloride or sulphate was needed. In *E. coli* addition of minute amounts (10^{-4} M) of sodium salts rendered the accelerating effect of potassium independent of the nature of the anion. Conditions known to diminish the rate of penetration of metabolites into the bacterial cell (rising pH, low substrate concentration) rendered the accelerating effect of potassium more pronounced. The latter observation suggested regulation of permeability as a possible mode of action of the electrolytes. In order to test the validity of this assumption, the effect of electrolytes on the rate of uptake of labelled glutamate was examined.

The composition of the reaction mixture was as follows: 15 mgm./ml. (wet weight) of the bacterial cells, washed thoroughly with 0·25 M sucrose, 10^{-2} M of the electrolytes and 0·25 M sucrose.

Table 1. EFFECT OF CATIONS ON THE RATE OF PENETRATION OF GLUTAMATE INTO THE CELLS OF *E. coli* AND *P. tularensis*

Time	Counts/10 min.*									
	No electrolyte added		KCl		NaCl		LiCl		RbCl	
	E.	*P.*	*E.*	*P.*	*E.*	*P.*	*E.*	*P.*	*E.*	*P.*
30 sec.	40	36	240	210	50	80	50	80	70	150
3 min.	60	60	530	566	50	170	50	170	110	310
6 min.	70	80	500	560	140	260	130	260	160	410

* After the deduction of the background count (200/10 min.). 100 counts/10 min. represent approximately 3×10^{-3} μmole of glutamate.

After thermal equilibration (28° C.) 0·03 *M tris* glutamate and glutamate uniformly labelled with carbon-14 (0·01 μc./ml.) were added, samples of 3·0 ml. were withdrawn at various time-intervals, chilled to 0° C. and centrifuged (30,000*g*). The radioactivity of the well-drained but unwashed cell mass was determined by a method essentially identical with the procedure adopted by Krebs *et al.*[1].

Results which show the effect of various monovalent cations (tested as their chlorides) on the rate of increase of the radioactivity in the bacterial cell mass (*E. coli*; *P. tularensis*) are given in Table 1. The modifying influence of the anions on this process is shown in Table 2. It can be seen that potassium chloride in *E. coli* and potassium chloride and rubidium chloride in *P. tularensis* which accelerate the oxidation of glutamate also increased the rate of its accumulation. Cations which were found ineffective on the respiration also had no effect on the accumulation. A mixture of potassium and sodium nitrates was as effective as potassium chloride, while each compound separately accelerated neither accumulation nor the oxidation of the substrate. The nature of the anion affected respiration and accumulation in a parallel manner.

Table 2. EFFECT OF ANIONS ON THE RATE OF PENETRATION OF GLUTAMATE INTO THE CELLS OF *E. coli* AND *P. tularensis*

Time	Counts/10 min.*											
	No electrolyte added		KCl		KBr		KNO_3		K_2SO_4		KNO_3 + $NaNO_3$	
	E.	*P.*	*E.*	*P.*	*E.*	*P.*	*E.*	*P.*	*E.*	*P.*	*E.*	*P.*
30 sec.	40	70	190	200	110	250	80	68	190	60	180	—
3 min	70	100	480	540	120	542	150	260	410	270	410	—
6 min.	90	90	560	560	130	613	180	260	440	270	595	—

* After the deduction of the background count (200/10 min.). 100 counts/10 min. represent approximately 3×10^{-3} μmole of glutamate.

In view of similarity of effect of the ionic environment on the respiration and on the 'uptake' of the substrate, consideration has to be given to the possibility that the electrolytes regulate the rate of respiration by controlling a process directly connected with the penetration of the substrate.

It remains, however, to be shown that increase in radioactivity in the cell mass is due to the penetration of the substrate into the bacteria, and furthermore, that penetration is the rate-limiting factor in the reaction sequence.

Novel Action of Potassium on a Yeast and a Counteraction by Aluminium

A PAPER[1] from this laboratory described an improved method for the estimation of *Oospora lactis* Fres. (formerly known as *Oidium lactis*) in pressed bakers' yeast, using a medium consisting of ammonium succinate, mineral salts and agar. The method worked well with most yeasts, but one strain (*Saccharomyces cerevisiae* D.C.L. 557) prevented the growth of visible colonies of *Oospora* on the above medium. This effect has been further studied, and it has been found that the immediate cause of the inhibition was the presence in the medium of 2×10^{-2} *M* potassium (as the dihydrogen phosphate). This was demonstrated by excluding potassium from the medium, adding the phosphate as the sodium or ammonium salt. The mould then developed into dense colonies; these were not, however, quite so large as those grown on normal medium (containing potassium) in the absence of yeast. This reduction in size was due to the fact that *Oospora* required 3×10^{-4} *M* potassium ions for optimal growth on ammonium succinate, mineral salts, agar medium. When Yeast 557 was present, however, this concentration of potassium, added as sulphate or chloride to the medium (containing sodium or ammonium dihydrogen phosphate), inhibited the growth of the mould. The inhibition was largely overcome by the addition of 5×10^{-4} *M* aluminium (as ammonium alum) to the normal medium.

A similar effect was obtained with other salts of aluminium, but not with salts of other multivalent elements, calcium, magnesium, manganese or silicon. The concentration of aluminium required to counteract the inhibition indicated that the action was not a trace-element effect. In fact there was sufficient aluminium to envelop each yeast cell 10^3 times. The mechanism of the action of potassium and the counteraction by aluminium has not been elucidated.

The suggestion[2] that potassium might regulate cell permeability offered no obvious clue to the problem. Rossi[3] showed that potassium ions stimulated the oxidation of succinic acid in resting cells of *Escherichia coli* in the Warburg apparatus. It seemed possible that some oxidation product of succinic acid might be formed in this way by Yeast 557 and be inhibitory to the growth of *Oospora*. The addition to the medium of 4×10^{-3} *M* fumaric acid or of 4×10^{-2} *M* maleic acid produced no inhibition of the mould.

Detection of Uric Acid in the Tissue Homogenates of Earthworms

LESSER[1], working on *Lumbricus agricola* and *Allolobophora foetida*, Ackermann and Kutscher[2] on extracts of tissues of earthworms, Delaunay[3] on excreta of earthworms, Heidermanns[4] on tissues of *Lumbricus*, Bahl[5] on excreta of *Pheretima*, Abdel Fattah[6] on tissue homogenate of *Lumbricus*, were all unable to detect the presence of even traces of uric acid in these worms. Only Cohen and Lewis[7] found that the non-protein nitrogen excreted by *Lumbricus* *terrestris* was mainly in the form of ammonia together with small traces of both urea and uric acid.

Uric acid is known to be very sparingly soluble in water, and it is possible that the previous authors, working with water extracts of tissues, have overlooked the presence of uric acid.

As uric acid is readily soluble in lithium hydroxide, the following technique was used in the present study on *Allolobophora caliginosa* f. *tropezoides*. The worms were homogenized with water in a Potter–Elvehjem[8] homogenizer, and the homogenate was made up to a known volume. Homogenate portions were digested in a Kjeldahl apparatus for estimating its total nitrogen content, to relate the concentration of the homogenate constituents to the total nitrogen of the tissues. This was carried out since the fresh weight of the worms is not constant, owing to the different rates of desiccation of the worms. Another homogenate portion was centrifuged and the supernatant was tested for uric acid using Brown's[9] method. The residue was afterwards dissolved in 1 per cent lithium hydroxide and recentrifuged, and the centrifugate was examined again for uric acid. Both uric acid values, the water-soluble and the lithium hydroxide-soluble, were added together and related to the nitrogen content of the tissues of the worms.

It was found that the uric acid content of the tissues of the worms examined was 3·34 mgm. per gm.[3] tissue nitrogen. Further details will appear elsewhere.

Electrical Noise from 'Polarization Cells' and from Human Tissues

IN electromyography, metal electrodes are attached to the skin to detect the electrical changes associated with the activity of the underlying muscles. It has often been stated that a resting muscle is 'electrically silent'. However, if the amplifier noise is reduced sufficiently, electrical fluctuations of a random nature with an amplitude of about 5 μV. (peak to peak) are observed even when the subject is lying comfortably at rest on a bed[1]. The first possible explanation that comes to mind is that these fluctuations represent the random thermal noise of the source, which in this case is the skin and muscle tissue in series with the electrodes. This suggestion has been tested by simultaneous measurements of the impedance between the electrodes and the spectrum of the fluctuations.

Analysis of measurements of the impedance of the tissues with the aid of Cole impedance diagrams[2] before and after rubbing away the horny layer of the skin confirmed that the skin and underlying tissues could each be represented by a fixed resistance in parallel with a 'polarization cell' containing a resistance and capacitance the values of which were dependent on frequency. The next problem was, therefore, to estimate the noise produced by a 'polarization cell'. This was investigated experimentally. A stainless-steel concentric needle electrode, consisting of a hypodermic needle 0·64 mm. in diameter with a central wire 0·126 mm. in diameter, insulated by 'Araldite' cement, dipped into 1 per cent sodium chloride, was chosen as a convenient 'polarization cell' the impedance of which was almost entirely attributable to the metal-solution interfaces and only to a negligible degree to the resistance of the electrolyte. The impedance was measured at a given frequency at a current density of a few m.amp. per sq. cm. of electrode area, and the noise generated by the cell in a narrow band centred at that frequency was determined with the aid of the low-noise amplifier and a Muirhead–Pametrada wave analyser. The cell was then replaced by its equivalent impedance consisting of a resistance in parallel with a condenser, and the noise again measured; this was found to be equal within the expected error of the measurements (about 4 per cent), to the noise produced by the cell, in the range 125–4,000 c./s. At higher frequencies the noise produced by the cell was too small to observe above amplifier noise. At lower frequencies the cell produced more noise than the equivalent impedance. This was probably caused by slight movements of the needle set up by vibration; the discrepancy was reduced, though not eliminated, by fixing the needle more rigidly to the vessel containing the solution. It was concluded tentatively that the component at a given frequency of the noise produced by a 'polarization cell' is equal to the component of the thermal noise arising from the equivalent impedance measured at that frequency. Incidentally, this confirms an observation made by Wien as long ago as 1896[3] that the impedance of a metal-electrode system is independent of the current density up to a certain limit of a few m.amp. per sq. cm. (Above this limit the impedance decreases with increasing current density.) Indeed, the noise measurement may be regarded as a method of determining the impedance at the lowest possible current density, that is, the current density caused by thermal agitation.

Since the frequency-dependent component of the tissue impedance may have a physical basis similar at any rate in part to a polarization impedance, it seemed reasonable to expect that the tissues would generate the thermal noise which could be calculated from the values of their measured impedance. In fact it was found that the tissue noise was greater than this expected value, particularly at low frequencies. Measurements with surface electrodes 1 cm. in diameter before and after rubbing away the horny layer of the skin made it possible to show that both skin and underlying tissues contributed to the 'excess' fluctuations. Spectra of the excess fluctuations for three different subjects, for rubbed skin, are shown in Fig. 1. Above about 1,000 c./s. the components of the fluctuations were too small to measure in the presence of the amplifier noise. Excess fluctuations were also found when the needle electrode was inserted into a resting muscle.

It is possible that the excess fluctuations are caused in part by small movements of the electrodes relative to the tissues, by fluctuating streaming potentials set up by the ebb and flow of blood in the small vessels[4], by the miniature end-plate potentials

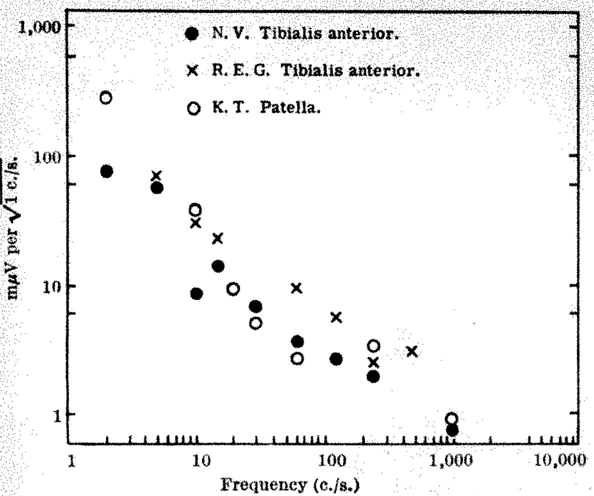

Fig. 1. Spectra of the excess fluctuations detected by silver suction electrodes 1 cm. in diameter, placed 5 cm. apart on the sites indicated. The skin was scraped with fine sandpaper to remove the horny layer, and rubbed with electrode jelly before the electrodes were attached. The excess fluctuation is the total observed fluctuation less the contributions caused by amplifier noise and thermal noise in the tissue impedance. The ordinate represents the square root of the mean square potential difference in a band 1 c./s. wide

reported by Fatt and Katz[5], by the 'biological noise' reported by Brock, Coombs and Eccles[6], and by discharges in sensory nerve fibres. The fact that they are found when the electrodes are placed over non-muscular sites such as the patella suggests that they are not caused by the continuous firing of a few motor units in a muscle. This result is of interest in relation to the hypothesis that muscular 'tone' is caused by just such a background of active contraction, persisting in a normal muscle even when resting, and supports the view expressed by Ralston[7] that this classical concept of tone should be reconsidered.

Nervous Control of Cilia in Amphioxus (*Branchiostoma*)

One of the clearest cases of the nervous control of cilia was provided by Fedele's[1] work upon the cilia of the gill bars of the pelagic tunicate *Doliolum*; in the sessile tunicates also it seems that the gill bar cilia may be inhibited by the peripheral nervous system, for they may be observed to beat intermittently in the intact animal, and D. B. Carlisle (personal communication) has found that several species of sessile ascidian occasionally show both branchial apertures open with no water current passing through the atrium, that is, the gill bar cilia are presumably at rest. Knight-Jones[2] has shown that in the Enteropneusta the gut cilia exhibit bursts of activity alternating with periods of rest; in this group, the gill bar cilia also appear to be under the control of the nervous system.

It is interesting that all these animals are more or less closely related to the Acrania, and that all feed in a somewhat similar manner. It is not surprising that in amphioxus also the cilia producing the feeding current are under nervous control. In amphioxus, however, the evidence is perhaps more striking, for ciliary inhibition may be produced by a specific stimulus, and it may be observed in the intact animal; in dissected preparations (as, for example, in the experiments upon the Enteropneusta), the dissection inevitably involves derangement of the normal blood supply to the ciliary tissue, and it is not certain, therefore, that the ciliary inhibition may not be a secondary effect.

When a small amphioxus is placed in a Petri dish of sea-water under a binocular, the lateral cilia of the gill bars are clearly visible through the transparent body-wall. Even in the largest animals some of the gill apparatus is visible. When the animal is anæsthetized with dilute solutions of benzamine hydrochloride, magnesium chloride, or urethane, all the lateral cilia of the gill bars exhibit metachronal beat, of the kind discussed by Knight-Jones[3].

Isolated parts of the gill apparatus also show metachronal beat when anæsthetized.

In the normal animal, which has been feeding, it is invariably the case that some parts of the gill apparatus do not exhibit metachrony. The cilia of some parts of some gill bars or of all of some gill bars are either found to be at rest or else feebly vibrating non-metachronously. Upon the addition of anæsthetic, the parts of the gill apparatus which are at rest begin to beat and soon achieve metachrony.

In the normal unanæsthetized animal, certain stimuli, for example, the addition of carmine suspensions to the water, result in complete or nearly complete cessation of ciliary beat. This takes place rapidly; a minute after the carmine particles have entered the atrium, all the cilia are at rest. If the animal is now placed in an anæsthetic, metachronal beat is resumed as soon as anæsthesia has proceeded so far that the reflex responses of the buccal cirrhi and velar tentacles have been abolished. Addition of carmine suspensions to anæsthetized animals does not inhibit the metachronal beat.

These facts strongly suggest that the lateral cilia of the gill bars (those chiefly instrumental in producing the feeding current) are under nervous control, and that this control is inhibitory upon a fundamental metachronal rhythm. It is interesting that other ciliary tracts which are concerned in a subsidiary way with the feeding process, the wheel organ and the pharyngeal cilia of the gill bars are never observed to stop beating under any stimuli such as the addition of carmine particles.

It is less easy to observe the cilia of the gut in the intact animal, but in very small specimens the metachronal beat of the gut cilia can be observed; it does not appear to alter when the lateral cilia of the gill bars are inhibited.

The significance of the nervous control of the cilia producing the feeding current in the normal life of the animal is not certainly known, but it is probable that it is related, as Rice[4] long ago suggested, to intermittent patterns of activity in the feeding process. He supposed that amphioxus alternated feeding periods with periods of rest when it hid beneath the sand, and pointed out that this hypothesis implied that the animals could in some manner control the rate of beating of the cilia producing the feeding current.

The manner in which this control is exerted is extremely obscure; it is not known, for example, whether the rate of beat is controlled, or whether the control is simply of an on–off type. In amphioxus, unlike the other early chordate-like groups in which nervous control of cilia has been suggested, the peripheral nervous system is fairly well known; Dogiel[5] and Kutchin[6] have shown that there are many multipolar nerve cells lying upon the gill bars, and under the endostyle; I have shown that it is probable that these cells are connected with the central nervous system by their own axons[7]. That metachrony is not resumed at the same parts of the gill bars where it was first inhibited, when an animal that has been in a carmine suspension is placed in anæsthesia, does not suggest that the inhibition can be a local effect, related to the dendrite fields of particular neurons.

A detailed account of these observations will be published elsewhere with other observations upon the muscular patterns in the feeding process of amphioxus.

Neurosecretory Cells in some Cirripedes

THE occurrence of neurosecretory cells or their products has not hitherto been demonstrated in the Cirripedia. By analogy with the situation in many other crustaceans the neurosecretory organs of which have recently been the object of much investigation, control of many of the metabolic processes in the Cirripedes might be expected to be under hormonal control originating in neurosecretory activities[1].

We have recently shown the presence of typical neurosecretory cells containing abundant granules (Fig. 1) that stain deeply with the paraldehyde–fuchsin of Gabe's modification[2] of Gomori's technique. In *Pollicipes polymerus* J. B. Sowerby, the cells are large (about 30–40μ largest diameter) and prolific in the sub- and supra-œsophageal ganglia where they appear to be localized in discrete areas. Release of the granules appears to take place both through the cell membrane and by axon transport. It has been possible to follow the development of these cells and the formation and discharge of the granules. Further, cross-sections of the sub-œsophageal, but no other ganglion, show discrete paired areas where the deeply staining granules are concentrated and nuclei are absent.

The following operculate barnacles have also been examined, *Balanus glandula* Darwin, *B. hesperius lævidomus* Pilsbry, *B. nubilis* Darwin, *B. rostratus* Hoek and *Chthamalus dalli* Pilsbry. In all these, deeply staining granules are found in the major ganglia but the neurosecretory cells are much smaller and less well defined than in *Pollicipes polymerus*; this could be related to the season when collected.

The investigation of neurosecretion in the Cirripedia would seem to offer a new and profitable approach to many problems of their physiology and ecology. Further, since most of the species, unlike almost all other crustacean groups, are hermaphrodite and yet normally cross-fertilizing, the relation of their neurosecretory activities to their reproductive activities presents problems of unusual interest, as does its relation to the uncommon moulting behaviour.

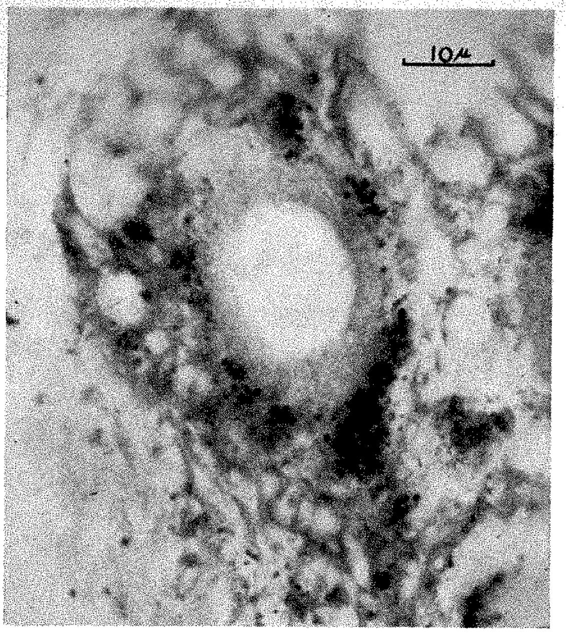

Fig. 1. *Pollicipes polymerus* J. B. Sowerby. Photomicrograph (green light) taken from transverse section of ganglion showing large neurosecretory cell. Paraldehyde–fuchsin stained; note large unstained nucleus and numbers of deeply staining granules around periphery, in blood spaces and in the axon hillock

A detailed account of this work and the results of further related observations will be published elsewhere.

Connective-Tissue Pigment of the Centipede, *Lithobius forficatus* (L.)

THE connective-tissue pigment of the centipede *Lithobius forficatus* is violet in colour and occurs in abundant granules in the connective tissue cells[1]. Little is known of its nature and properties. On dissecting the animal[2] it was noticed that the intensity of colour increased, implying that *in vivo* some of the pigment is in a colourless, reduced form. Interest in the pigment was renewed by the demonstration of a tissue-pigment with a redox colour change in the isopod Crustacea[3]. The pigment cells of the latter are of mesodermal origin, like those of *Lithobius*.

The pigment has been extracted by mild treatment and further purified by precipitation and chromatographic procedures. The absorption spectrum of the oxidized form, in neutral aqueous medium, shows a peak around 580 mμ and a trough around 495 mμ.

With decrease in wave-length beyond this point absorption increases, without incident, to a peak at 258 mμ, probably indicating the presence of nucleic acid. There is a shallow trough at 245 mμ, beyond which point absorption increases sharply. The reduced pigment is pale yellow in colour; in the visible range its absorption of light shows a monotonous increase as wave-length decreases.

The colours, and the absorption spectra of oxidized and reduced forms in the visible range, resemble those of hæmocyanin[4]. The resemblance extends also to solubility properties, both being soluble in water and being precipitated at about *p*H 5·0, the isoelectric point of a protein moiety. Phenolic amino-acids and arginine are demonstrable in the unhydrolysed pigment of *Lithobius*. It also contains about 0·2 per cent copper, that is, approximately the same concentration as in hæmocyanin.

The pigment therefore may prove to be a 'cytocyanin', related to hæmocyanin as myoglobin and the cytochromes are related to hæmoglobin. Until recently no such intracellular copper-pigment was recognized[4]. It is now known[5] that a number of copper-containing enzymes and pigments are closely related to hæmocyanin in colour and composition, and may occur intracellularly. The *Lithobius* pigment probably differs from these in its high concentration in the body and possibly in acting as a normal oxygen-mediator for the tissues generally, which carry a rich investment of the pigment-tissue. *In vitro* it is rapidly and reversibly reduced by chemical reducing agents, including ascorbic acid, but it remains oxidized down to very low oxygen tensions. It catalyses the oxidation of hydroquinone, though not of tyrosine. It appears to be an active redox agent *in vivo*.

The pigment differs from hæmocyanin in several essentials. The colour is normally violet, and not blue, and the absorption spectrum in the visible range differs in detail. In the ultra-violet range the spectrum differs considerably, showing peaks at 346 and 278 mμ in hæmocyanin[4]. The 278-mμ peak indicates a higher percentage of protein than in the *Lithobius* pigment, and this is confirmed by the estimation of total nitrogen. The pigment is more stable than hæmocyanin, for example, towards strong alkali; it is not decolorized by carbon monoxide or by hydrocyanic acid and is only slowly destroyed by trichloracetic acid at 95° C. It withstands boiling for a long period: in this it resembles phosphoproteins and, in fact, contains abundant phosphorus. Like phosphoproteins it redissolves on the acid side of its isoelectric point, giving an apricot-coloured solution. The hæmocyanin of *Helix* remains greenish-blue under this condition.

I am greatly indebted to colleagues in the Department of Biochemistry for the use of spectrophotometers.

A Two-stage Transfer of Pathogenicity between the *MEL* and *NWS* Strains of Influenza *A* Virus

IN genetic interaction between the *MEL* and *NWS* strains of influenza *A* virus it is convenient to regard the production of specific lesions in the chick embryo and pathogenicity for the mouse which has been inoculated intra-cerebrally with the virus as separate heritable characteristics, both of which are transferable from *NWS* to *MEL*[1]. It has been a feature of Australian work that recombinant, *N–M*, strains produced by double infection of the allantoic cavity of the chick embryo are not pathogenic for the mouse (Fraser, K. B., and Burnet, F. M., unpublished work). On the other hand, American work records combination forms, produced in the fertile egg, which are virulent for the mouse[2], but the methods of production of *N–M* strains in the two laboratories are not strictly comparable. Our techniques concentrated on limiting the time of virus production to a short infectious cycle of about eight hours, which was initiated in the washed allantoic cavity[3] and from which the original inoculum was largely removed before the new yield became available, whereas American methods used both the washed and the intact allantois, variable reproductive times up to forty hours and inocula irradiated with ultra-violet. The precise source of the most virulent recombinant of the *MEL* type is not described; but in general, transfer of pathogenicity was most effective with small doses and after long reproductive cycles[2]. The most likely explanations of the failure of our hybrid strains to acquire pathogenicity to the mouse were thus the washing out of the allantoic sac or the limiting of reproduction to one cycle.

In order to investigate the results of multiple cycles of double infection, each of three hybrid *N–M* strains which had originally been isolated from double infection of the chick embryo with *MEL* and *NWS* and which were non-pathogenic on intracerebral inoculation of the mouse, was subjected, in the chick allantois, to a series of four separate growth-cycles of nine hours duration in the presence of an adequate inoculum of the pathogenic 'parent' *NWS*. Groups of three eggs were used and the presence of double-neutralizing hæmagglutinin in all eggs was taken as a criterion of successful double infection[4]. Between each cycle of infection the *N–M* strain was re-isolated from the pooled allantoic fluids of each group by two allantoic passages at the limit of infectivity in the presence of sufficient anti-*NWS* serum to neutralize $10^{4\cdot5}ID50$ of *NWS* virus. This ensured that the heterogeneous product of each infectious cycle was not passed from one pool of fluids into the next according to the following scheme:

$$\left.\begin{matrix}N\text{–}M\\ \times\\ NWS\end{matrix}\right\}\begin{matrix}\text{Pool}\\ 1\end{matrix}\quad 2LD\quad \left.\begin{matrix}N\text{–}M\\ \times\\ NWS\end{matrix}\right\}\begin{matrix}\text{Pool}\\ 2\end{matrix}\quad 2LD\quad \left.\begin{matrix}N\text{–}M\\ \times\\ NWS\end{matrix}\right\}\begin{matrix}\text{Pool}\\ 3\end{matrix}\quad 2LD\quad \left.\begin{matrix}N\text{–}M\\ \times\\ NWS\end{matrix}\right\}\begin{matrix}\text{Pool}\\ 4\end{matrix}$$

$2LD$ = 2 passages at limiting infectivity in anti-*NWS* serum.

$\overset{\times}{NWS}$ = 9-hr. growth cycle in the presence of *NWS*.

There were three such series, one for each strain of *N–M* virus, and a pool of three fluids was preserved from each cycle in all series. The mouse pathogenicity of limit dilution fluids from pool 4 of each series was compared with that of the original *N–M*'s in the first instance. Test fluids were grown in anti-*NWS* serum. As Table 1 shows, each fluid from the fourth

Table 1. Comparison of Intra-cerebral Pathogenicity in Mice of Original and Fourth-cycle *N–M* Virus Strains

	Starting fluids	Fourth-passage fluids
Series 1	0/6	1. = 2/6* (+ 1 sick) 2. = 3/6 (+ 1 sick)
Series 2	0/6	1. = 2/6 (+ 1 sick) 2. = 3/6 (+ 1 sick)
Series 3	0/6	1. = 3/6 (+ 1 sick) 2. = 2/6 (+ 1 sick)

* Fractions indicate dead/survivors.

pools in the three series was pathogenic to mice. To eliminate spontaneous mutation to neuro-tropism as a cause and also contamination by *NWS* virus, the same *N–M* strains in high dosage, $10^{4 \cdot 0} ID50$, were given four successive cycles of four days each in mouse-brain. They failed to become pathogenic to mice and no *NWS* grew.

Since *N–M* strains are pathogenic for the chick when first isolated, these results are evidence of at least a two-stage transfer of pathogenicity between the *NWS* and *MEL* strains of influenza virus. This might be expected from the distribution of virulence in recombinant influenza viruses which Burnet has stressed[5].

Gestational Changes in Connective Tissue in the Ewe

In a previous communication[1], various gross changes in the pelvic region of the pregnant ewe were described. Studies on pelvic relaxation in this animal have now been extended to include microscopic examination of pelvic connective tissue structures at different gestational stages.

Histological preparations were made of samples from the broad ligament of the uterus, the sacrosciatic ligament, the ischiococcygeus muscle and its tendon of origin, the fibrous portion of the sacroiliac joint, the lumbosacral joint, and the pubic symphysis. For comparison, similar tissue from an area outside the pelvic region was included, the gastrocnemius muscle and the tendon of origin of the deep flexor muscle of the lower limb being selected for this purpose. In addition, the connective tissue layers in the different parts of the urogenital tract were examined.

Several standard connective tissue stains, including a silver impregnation method, were used. Histochemical techniques were not applicable in this instance. The observations have thus been confined largely to fibroblasts and collagen fibres.

For the broad and sacrosciatic ligaments, samples were taken from a total of nine non-pregnant ewes, two in œstrus and the others in mid-cycle, 29 pregnant animals at different stages throughout gestation, and five immediately post-partum. The remaining tissues were available from four of the non-pregnant ewes and nine of the pregnant ewes at stages between 88 days and full-term.

Marked effects of pregnancy were observed in the connective tissue of the broad uterine and sacrosciatic ligaments, the ischiococcygeus muscle and the sacroiliac joint. Similar microscopic differences occurred in the connective tissue of the uterus, cervix and vagina of pregnant and of œstrous ewes, in comparison with non-pregnant animals in the mid-phase of the œstrous cycle. No such changes were seen, however, in the pubic symphysis, the lumbosacral joint, the Fallopian tubes, bladder or ureters, or in the connective tissue of the gastrocnemius muscle and the tendon of the deep flexor of the lower limb.

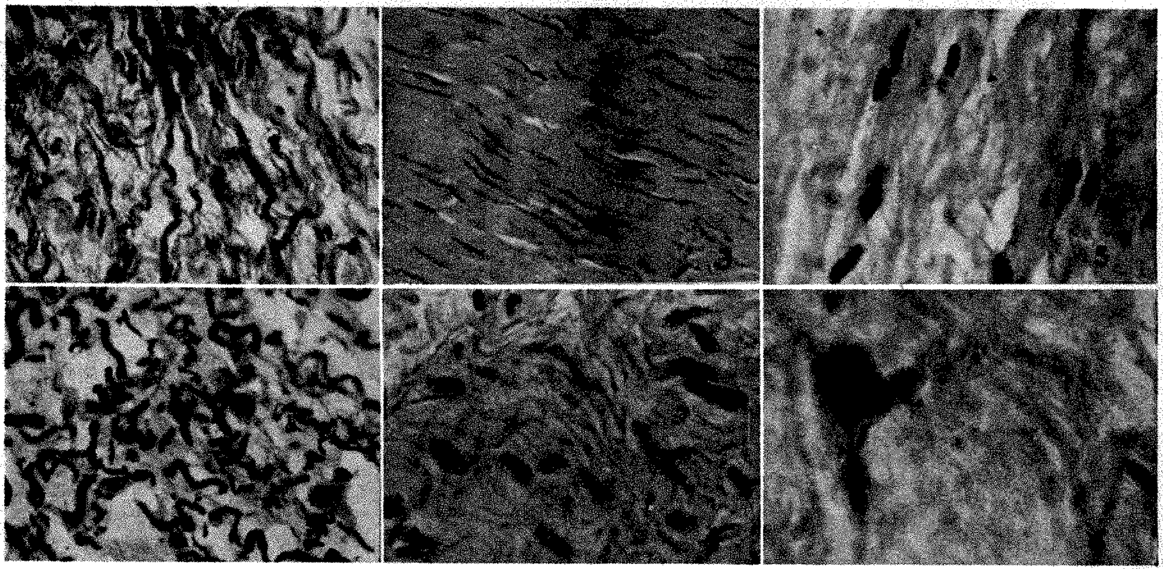
These gestational effects revealed themselves particularly in intense activity of the fibroblast cells. The most pronounced changes were seen in the broad ligament, in which the fibroblast changes were accompanied by disappearance of fibres staining with 'collagen' dyes, such as light green, and the appearance of argyrophil fibres (Figs. 1 and 2). A considerable relative increase in ground substance also occurred, the fibres and cells in sections from full-term ewes being sparsely distributed through the matrix, in comparison with preparations from non-pregnant animals. Similar, although less extensive, changes occurred in the other affected structures (Figs. 3 and 4).

In connective tissue from non-pregnant ewes, the fibroblasts consisted of small dense nuclei, with no visible cytoplasm (Fig. 5). In the broad and sacrosciatic ligaments, for which samples were available at early gestational stages, changes in the fibroblasts were apparent by 60 days. The nuclei were now oval to round and less dense than in non-pregnant preparations. These nuclear changes, which continued progressively throughout pregnancy, were associated with increasing amounts of visible cellular cytoplasm. At full-term, these cells were large, with heavily stained cytoplasm which, especially in the broad ligament, were commonly extended into long pseudopodial processes (Fig. 6).

In terms of parturition problems in the ewe, these observations are significant in that the affected tissues are chiefly those concerned in enlargement of the pelvic canal prior to parturition. Previous studies[2] showed that relaxation of the sacroiliac joints results in potential horizontal movement of the sacrum. Gross anatomical dissections (unpublished work) have indicated that the sacrosciatic ligament and the ischiococcygeus muscle are important components of the pelvic outlet in the ewe. Changes in the connective tissue of the reproductive tract are not unexpected in view of its direct role in pregnancy.

With regard to the structure of the pelvic tissues which do not change, the bony surfaces of the ischiopubic symphysis are united by a single layer of hyaline cartilage, no fibrous tissue being present; in the lumbosacral joint, the collagenous annulus lamellosus contains a sparse distribution of small pycnotic nuclei with no visible cytoplasm which do not closely resemble the fibroblasts of the other tissues described. The increased flexibility of this joint, which has previously been observed in pregnancy, may thus be an indirect effect due to changes in ligaments associated with this region.

Many histological and especially histochemical studies have been carried out on the pubic symphysis of the guinea pig and mouse in pregnancy, experi-



Figs. 1 and 2. Broad ligament. (1) Non-pregnant; collagen fibres only. (2) Pregnant, full-term; many argyrophil fibres, collagen scarce. (Silver impregnation with Weigert's hæmatoxylin and light green. × 375)
Figs. 3 and 4. Sacrosciatic ligament. (3) Non-pregnant; flattened fibroblast nuclei with no cytoplasm, dense parallel collagen fibres. (4) Post-partum; clear oval fibroblast nuclei with much cytoplasm, loosened collagen fibres. (Weigert's hæmatoxylin and van Giesen. × 375)
Figs. 5 and 6. Broad ligament. (5) Non-pregnant; small dense fibroblast nuclei with no cytoplasm. (6) Pregnant, full-term; oval-round clear fibroblast nuclei, pseudopial cytoplasm. (Weigert's hæmatoxylin and van Giesen. × 780)

mental evidence indicating that the changes are due to hormone action (see ref. 3 for reviews).

Mechanical loosening of the sacroiliac joints has been described for these species and for some other mammals, including man, in which relaxation of the pubic symphysis also occurs, and cattle. No reference can be found to microscopic gestational changes in the sacroiliac joints of any species, or to other pelvic connective tissues which might be of importance in parturition.

Other investigations concerning hormones and connective tissue have been concerned chiefly with disease processes (see ref. 4 for review). Relatively less attention has been given to the different connective tissue components in normal variations of body processes, such as pregnancy and the œstrous cycle.

Thus, in addition to their possible application to obstetrics in ewes and other mammals of social or economic importance, the findings from this investigation are of some interest in connective tissue physiology in general. It is well established that the fibroblast cells are responsible for the production of collagen fibres and that under proliferative conditions, such as tissue culture and wound healing, the fibres are at first argyrophilic, losing this capacity as they mature and acquiring instead an affinity for standard 'collagen' stains. The changes in the broad ligament of the pregnant ewe emphasize the fact that in the normal mature animal collagen is not in a static state, but under suitable stimulus is capable of reversible change, to form argyrophil fibres and vice versa. The regional specificity of response of the connective tissues suggests a differential sensitivity of fibroblast cells to the hormones of pregnancy.

Further studies are in progress, using histochemical as well as histological methods, to determine the gestational effects on other connective tissue components, such as the ground-substance and mast cells.

These investigations were carried out at the Anatomy School, University of Cambridge. A full account will be submitted for publication elsewhere.

Hæmoglobins in Monkeys

We recently described[1] the finding of some abnormal hæmoglobins in two species of monkeys. Work has continued since then, and we wish to report some further abnormal findings. All but one *Cercocebus albigena* were collected within a few miles of Epulu in the Belgian Congo.

The numbers examined in the different species of monkeys can be seen from Table 1.

The doubtful specimen of *Cercopithecus mona* and one of *Cercocebus albigena* are so designated in spite

Table 1

Species	No.	Result of paper strip electrophoresis of hæmoglobin solutions at pH 8·6
Cercopithecus mitis	2	Both normal
,, *ascanius*	3	All normal
,, *mona*	7	6 normal and 1 doubtful
,, *l'hoesti*	1	Normal
Cercocebus albigena	2	Both abnormal
,, *galeritus*	4	All abnormal
Papio doguera	1	Normal

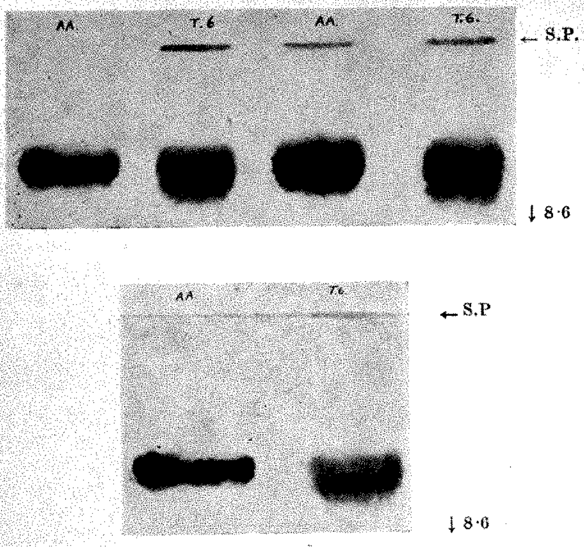

Fig. 1

of the actual numbering of the bottles. Because the hæmoglobin actually labelled as *C. mona* behaves exactly like seventeen other *Cercocebus albigena* samples we have assumed that the numbers were inverted in the field. Both animals were shot on the same day.

Cercopithecus mona. One specimen (*T*.6) gave a blurred pattern and appeared to have a forward component running slightly faster than the normal. This blood was in poor condition when it arrived in the laboratory and contained quite an amount of methæmoglobin. However, since methæmoglobin usually causes slowing of a specimen at *p*H 8·6, it seems probable that this specimen does contain a fast-running component. Its true position on electrophoresis remains uncertain. Fig. 1 shows *T*.6 in comparison with a normal blood.

Cercocebus galeritus. All four specimens from this species (which included a mother and son) were identical in pattern. The hæmoglobin separated into two distinct components. The faster component was the smaller of the two and lay just behind the normal position in the same place as the abnormal hæmoglobin of *Cercocebus albigena*. The slower component was the larger of the two and lay just behind human hæmoglobin *S* or *D*. Fig. 2 shows a sample of hæmoglobin from *Cercocebus galeritus* (*T*.12) running between human sickle-cell trait on the left and a normal blood on the right.

Cercocebus albigena. Both specimens were abnormal and showed exactly the same pattern as the sixteen specimens from this species previously described[1]. Since our earlier communication was written, a sample of *Cercocebus albigena* has been sent to Dr. H. Lehmann. He reports that on paper electrophoresis at *p*H 8·6 it lies slightly nearer the normal or *A* position than human hæmoglobin *G*.

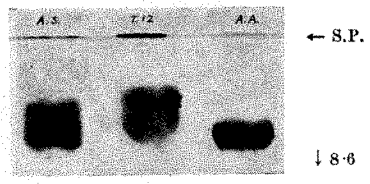

Fig. 2

The solubilities of the hæmoglobin solutions from seven *Cercocebus albigena* were determined in 2·58 *M* phosphate buffer; they were 2·60, 2·66, 2·72, 1·63, 2·23, 2·84, 2·32 gm./litre. The hæmoglobin solubilities of six *Cercopithecus ascanius* were: 2·65, 2·23, 2·76, 2·07, 1·51, 2·09 gm./litre. It seems that the slow-moving hæmoglobin of *Cercocebus albigena* does not differ appreciably in solubility from the normal-moving hæmoglobin of *Cercopithecus ascanius*.

The small size of the sample of *Cercocebus galeritus* does not give enough information to decide whether the two electrophoretic components are the effect of alleles or or fixation of genes at one or more loci. The second condition has not been observed in man. If the first is the case, both alleles are probably of high frequency in the population. All four specimens were part of the same group and were collected on the same day. The collection of more animals of this species would be of great interest.

If it should prove possible to cross-breed these two species of mangabeys, more evidence on the genetic control of their hæmoglobins could be accumulated. Zuckerman[2] has reported numerous examples of viable hybrids of different species, and even genera, from the records of zoological gardens. At present the chromosomal complements of both species are being studied to assess their suitability for hybridization experiments.

This study was assisted by a grant from the Wenner-Gren Foundation for Anthropological Research.

Hormonal Regulation of Reproduction in the Milkweed Bug, *Oncopeltus fasciatus* (Dallas)

Reproductive processes in insects are controlled by hormones[1]. The corpus allatum has for some time been known as an organ of internal secretion necessary for the normal development of eggs in many insects; in some species it also influences the secretion from accessory sex glands. The medial groups of neurosecretory cells in the brain have been demonstrated to have a hormonal influence on egg development in the fly *Calliphora*[2].

In the milkweed bug, *Oncopeltus fasciatus*, the corpus allatum is an unpaired organ situated closely behind the corpora cardiaca and the hypocerebral ganglion. This organ complex, which is intimately associated with the walls of aorta, has nervous connexions with the pars intercerebralis region of the brain, the subœsophageal ganglion, the stomodæal nervous system, and probably the tritocerebrum. The nervi corporis cardiaci I originate from two groups, each consisting of five neurosecretory cells, close to the median line in the pars intercerebralis region of the brain. These cells, the so-called *A* cells[3], which stain dark purple with the aldehyde-fuchsin technique, are visible in the living adult, and are distinct from other types of neurosecretory cells in the brain. Extirpation of the *A* cells was tried in 149 females, adult age

PHYSICS Dept.
Upper Circular Rd., Calcutta

less than 1 hr.–2 days, and in 59 males, adult age 2–12 hr. The operated animals were kept separately at about 30° C. Of the operated females 48 survived and were killed at intervals of 10–146 days after the operation. 18 males survived and were examined at intervals from 10–80 days after the operation. 43 of the surviving females produced mature eggs, and in the males the reproductive organs looked normal. Thus the extirpation of these cells, when performed in young adults, does not prevent egg development, a result which is supported by similar experiments in phasmids[4]. Quantitative differences, namely, a reduction in the number of eggs produced, were observed in females deprived of the *A* cells as compared with normal animals or with operated controls. In females with a complete removal of the *A* cells, corpus allatum was usually of subnormal size. As in *Calliphora*[2], the neurosecretory cells in the brain seem to activate the corpus allatum.

In females allatectomized during the first day of adult life, normal egg development did not take place, and secretory material was not visible in the oviducts. Implantation of one corpus allatum taken from a sexually mature donor induced egg development in allatectomized individuals. Thus the corpus allatum seems to be necessary for normal egg development and oviducal secretion in *Oncopeltus*. The reproductive organs of allatectomized males had a normal appearance.

Starvation usually prevents egg development in *Oncopeltus*. This is due to an insufficiency of corpus allatum in starved individuals. Implantation of one corpus allatum taken from a sexually mature donor induces egg development in animals deprived of food[5].

The regulatory function of the corpus allatum in starved females was studied in a series of experiments performed on animals during the first day of adult life. The operated specimens were given only water and were examined 10 days later. Implantation of one corpora cardiaca–corpus allatum complex taken from a newly emerged female induced egg development in 10 out of 20 surviving specimens. The results obtained after implantation of a complex consisting of brain, subœsophageal ganglion, and corpora cardiaca–corpus allatum from a newly emerged specimen depended upon the innervation of the corpora cardiaca–corpus allatum complex in the implant. If the connexions between this complex and the head ganglia were severed before implantation, 16 out of 28 specimens produced eggs, whereas this happened in only 4 out of 24 females which received implants where the nerves were left intact. Other experiments where the starved female had its own corpus allatum denervated also resulted in a stimulation of egg development. Thus in starved female *Oncopeltus* the corpus allatum seems to be inhibited by its nervous connexions to the brain.

It has been emphasized that the corpus allatum is not an autonomous organ, but that its activity is under the control of the central nervous system[6]. The present report indicates that in *Oncopeltus* this holds for both fed and starved females.

Laboratory Variations in Mortality of the Mosquito, *Culex fatigans* Wied., exposed to DDT

It is a common experience that in the same laboratory the susceptibility of test insects to insecticides varies from one occasion to another, but few attempts appear to have been made to study the causative factors in detail. In these laboratories, we have investigated the variation in the susceptibility of *Culex fatigans* Wied. to DDT since September 1949. In view of the recent communication of Burnett[1] describing the influence of atmospheric humidity on the mortality-rate of mosquitoes exposed to certain residual insecticides, our results may be of interest.

Our experiments were carried out with the insects drawn from a colony which was established from a single egg raft on September 17, 1945[2]. The breeding of insects as well as the assay of toxicity were carried out in a partially conditioned room in which, while the variations in temperature and humidity during any one day or succeeding days were not appreciable, they varied particularly in respect of humidity in the different months or seasons of the year. Over a period of seven years ending September 1956, the temperature and relative humidity ranged between 80° and 90° F. and 48 and 92 per cent respectively. Female mosquitoes 40 ± 5 hr. old were exposed at fortnightly intervals to filter papers impregnated with solutions of pure *pp*′-DDT in liquid paraffin in varying concentrations. The contact period was 1 hr., and observations on mortality were recorded 24 hr. afterwards. The mortality of mosquitoes in the control sets was nil. In Fig. 1 are presented the values of *LD*50 and of relative humidity and temperature on the days of assessment. For comparison with Burnett's results[1], the rainfall also has been indicated.

The results show that while such variations in temperature as there have been cannot account for the rise and fall in the values of *LD*50, relative humidity has a positive role. With higher humidities, particularly during the period of August–October in any year, greater values of *LD*50 are registered. With lower humidities during November–February the values for *LD*50 are also lower. In this connexion, the results obtained by Barlow and Hadaway[3] are of interest.

In order to provide confirmatory proof of the role of humidity in influencing the mortality, two experiments were conducted at the same temperature, 29 ± 1° C., but at two different controlled levels of humidity: 49 ± 6 per cent and 88 ± 4 per cent. Pupæ of *C. fatigans* drawn from the laboratory culture were placed in the respective humidity cabinets, and on emergence the adults (40 ± 5 hr. old) were exposed to the filter papers impregnated with varying concentrations of *pp*′-DDT. Dosage–mortality relationship is shown in Fig. 2. It will be seen that humidity bears an inverse relation to the mortality affected.

The work of Burnett[1] and the earlier work of Bordas and Navarro[4] have shown that with dieldrin and BHC the susceptibility of certain species of *Anopheles* is enhanced by an increase in relative humidity. The results described above with DDT using *C. fatigans* show a reverse trend. The difference can perhaps be understood on the basis of two competing influences coming into operation. One of these is connected with the availability of the insec-

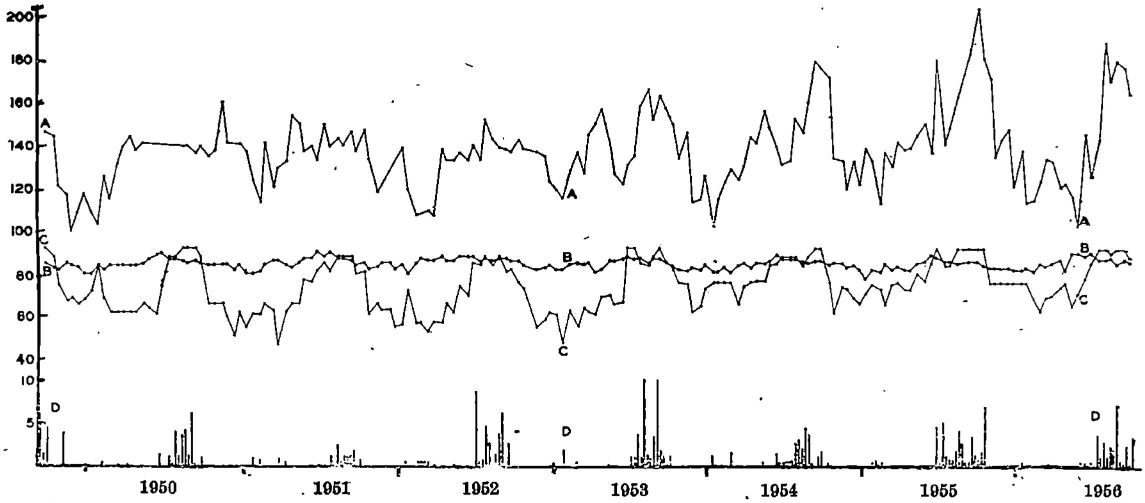

Fig. 1. Laboratory variations in mortality of the mosquito, *Culex fatigans* Wied., exposed to DDT at fortnightly intervals. *A*, *LD*50 mgm./ft.^{2}; *B*, temperature (° F.); *C*, relative humidity; *D*, rainfall. (• denotes trace)

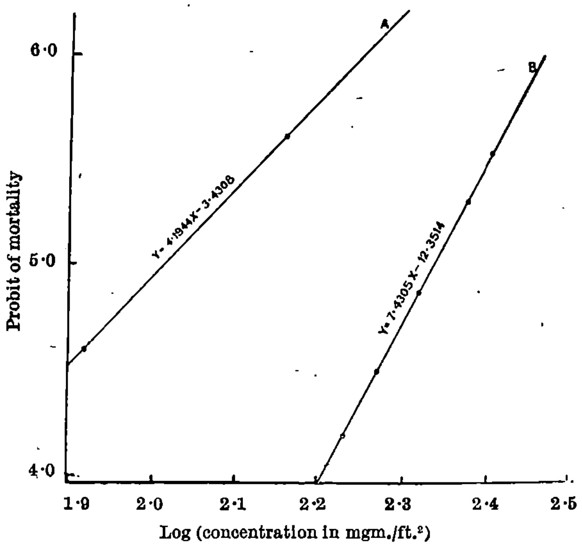

Fig. 2. Contact toxicity of *pp'*-DDT in liquid paraffin to *Culex fatigans* Wied. *A*, 29° C. ± 1° and 49 ± 6 per cent relative humidity; *B*, 29° C. ± 1° and 88 ± 4 per cent relative humidity

ticide on the surface treated, and the other is the variation in susceptibility of the test insect on account of the humidity of the environment. It appears that in Burnett's field trials[1] the former of the two factors takes a predominant role whereas in the experiments now reported the second factor takes the lead. Further work is in progress.

We thank Mr. Ali Ausat for technical assistance, and we are indebted to Dr. T. S. Subramanian, former chief superintendent of these laboratories, for interest in the work.

Reversibility of the Red – Far-red Reaction by Irradiation at Different Sites

Since the discovery that red light promotes and far-red light inhibits the germination of lettuce seeds[1,2] this reversible photoreaction has been studied in detail[3,4] and has been found to be identical with that involved in controlling flowering and other biological processes. Because of the widespread occurrence and importance of this reaction, a detailed understanding of its mechanism is of the utmost importance, and attempts to explain it have been made by a number of workers. Most recently, the available knowledge has been summed up by Hendricks in a formula of general terms[5]. The form in which this process is usually stated makes it appear that the same pigment molecules which, for example, have been brought to the far-red absorbing form by red radiation are directly reversed to their former state by the absorption of far-red light.

In all the experiments upon which this type of explanation is based, red and infra-red light were always given on the same side of the seeds. In order to discover whether an illumination active in reversing a previous light effect has to be applied at the same site or not, a simple experiment was carried out, that is, the seeds were turned over between the two kinds of illumination. 50–100 lettuce seeds were laid out in rows on dry filter paper and 2·5 c.c. water added. The seeds were allowed to imbibe for two hours in the dark at 25° C. and were then exposed to red light ('Sylvania' red fluorescent tube wrapped in red 'Cellophane') for various periods between 5 sec. and 10 min., the light intensity being about 19 kilo-erg./cm.^{2}/min. Immediately after the light treatment, the seeds were turned over with a tapered blunt spatula under a weak green safelight ('Sylvania' green fluorescent wrapped in yellow and green 'Cellophane'), while control lots were exposed to the same intensity of green light, but not turned over. Between 1·5 and 2·5 min. are required to turn over 50–100 seeds. Both the 'inverted' seeds and the controls received various amounts of far-red radiation (incandescent illumination filtered through blue and red 'Cellophane') 10 min. after the light treatment. Other controls were inverted, but not given subsequent far-red illumination.

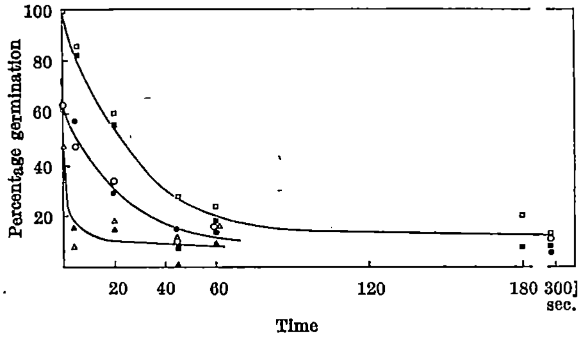

Fig. 1. Germination percentage of lettuce seeds after irradiation with red light, followed by far-red. □, Red-light treatment given for 60 sec.; ○, for 30 sec.; △, for 5 sec. Closed symbols: seeds received red irradiation on one side and far-red on the other. Open symbols: both light treatments given to same side

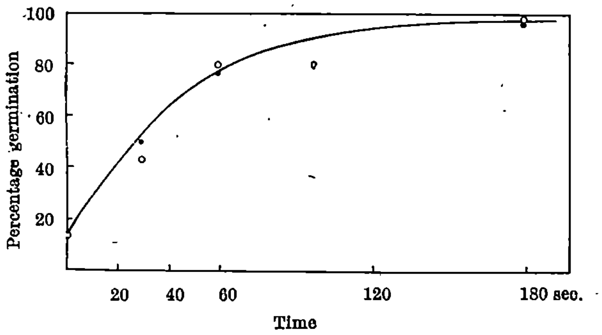

Fig. 2. Germination percentage of lettuce seeds after irradiation with far-red light for 1 min., followed by treatment with red light. Open and closed symbols as in Fig. 1

Fig. 1 shows that far-red radiation depresses the red light effect as well as, or even somewhat better, when applied on the reverse side of the seed than when given to the same side which had received the red light. The same is true for the reverse sequence of light irradiation, as can be seen from Fig. 2.

It is highly improbable that the seeds received the same amount of any irradiation on both sides owing to the optical properties of the wet filter paper. Neither can penetration of the light through the seed itself make this possible. When penetration of light through whole or bisected seeds was measured by photographing them on spectroscopic plates with the same light source as used in the experiments, it was found that at least 90 per cent of the incident light was absorbed by the seed halves.

The findings permit a number of interpretations: for example, the photoreceptor and/or photoproducts may diffuse rapidly after illumination throughout the seed. Another conclusion may be that although the photoreceptor molecules on one side of the seeds remain in the state determined by the first irradiation, illumination in a different site, that is, involving different photoreceptor molecules, will bring about reversal of the effect caused by the first illumination.

Further experiments, including the use of collimated light sources and irradiation with red as well as far-red light on both sides of the seed, will be carried out to gain more information on the system involved.

This investigation was part of the research carried out by one of us (S. K.) under the Atypical Growth Grant (*INSTR* 47H-962) to Dr. A. W. Galston, to whom our thanks for his interest and advice are due. The work of J. W. P. was supported by the John A. Hartford Foundation.

Effect of Transmitted Ribonucleic Acid from Healthy Pear Trees upon the Synthesis and Composition of Protein

QUITE recently it has been shown that ribonucleic acid, derived from tobacco mosaic virus, is infectious[1,2], that is, when inoculated into plants it induces typical metabolic changes.

In a previous paper the effect of uracil upon the synthesis of ribonucleic acid and the importance of the acid for protein synthesis in fruit trees was demonstrated[3]. The question now arises whether the effect of ribonucleic acid upon protein synthesis occurs *in situ* only, or whether it is possible, considering the above reports, to induce this effect in other trees by transmitting ribonucleic acid from one tree to another. This problem was investigated by testing ribonucleic acid derived from trees in a certain physiological condition upon those in a different physiological condition.

It is well known that pear trees grafted on pear seedlings differentiate flower buds much later than do those grafted on quince. Thus, though both types of trees are of the same age, they are in different physiological stages. This provides a situation suitable for the above tests.

Leaves were collected in May at the time of natural flower-bud differentiation from bearing pear trees (grafted on quince), and the *p*H quickly determined. For the extraction of ribonucleic acid, the leaves were minced in a Waring blendor for 1 min.; sufficient ice-cold water was added to produce a crude mash which was adjusted to the previously determined *p*H of the leaves. The minced material was washed several times with ice-cold 0·1 *N* sodium chloride and then with a 3/1 mixture of cold ethanol/ether. After separation of the organic solvent phase the material was transferred to twice its volume of ice-cold 0·4 *N* sodium chloride containing 0·5 per cent sodium dodecyl sulphate, and the whole adjusted to *p*H 7·5. The suspension, frequently shaken, was then kept for 6 hr. at 4° C. The aqueous fraction was separated, and the extraction procedure was repeated once more. The aqueous fractions from both extractions were combined and ammonium sulphate added to 0·4 saturation. The protein precipitate was separated and the supernatant was now shaken with an equal volume of ice-cold water-saturated phenol. The aqueous phase containing ribonucleic acid was decanted and the phenol was extracted with ether[1,2]. The refrigerated solution was adjusted to *p*H 6-3, and the acid was precipitated by saturation with sodium chloride. After separation the ribonucleic acid was dissolved in a *p*H 6 acetate buffer; the resulting ribonucleic acid–buffer solution was then applied to the non-bearing 'acceptor' (pear on pear) trees. The aqueous solution of ribonucleic acid was light yellowish, and Folin's phenol reagent[4] gave no indication of the presence of proteins.

The leaves of selected branches of the acceptor trees were first treated with 'Carborundum', and then immersed in the solution of ribonucleic acid, followed by gentle brushing of the leaf surface. This procedure was performed on two branches and repeated five times. Three weeks after the treatments leaves from bearing and non-bearing trees were collected. The dried leaves were then analysed for alcohol-soluble and -insoluble nitrogen fractions and amino-acid composition[3]. Table 1 summarizes the effect of the extracted and transmitted ribonucleic acid upon the soluble and insoluble nitrogen fractions of the acceptor.

Table 1. THE EFFECT OF RIBONUCLEIC ACID FROM BEARING PEAR-TREES UPON THE TOTAL; 'SOLUBLE' AND 'INSOLUBLE' NITROGEN OF NON-BEARING PEAR TREES

* Leaves of untreated bearing (pear on quince) trees.
† Leaves of untreated non-bearing (pear on quince) trees.
‡ Leaves of non-bearing trees treated with ribonucleic acid from bearing trees.
§ Leaves of non-bearing trees treated with degraded ribonucleic acid (the acid was boiled with 0·5 *N* potassium hydroxide before transmittance).

It is seen from Table 1 that the transmitted ribonucleic acid markedly effects the metabolism of nitrogen in the acceptor tissue. The absorption of total nitrogen into the leaves was considerably increased; the total level of protein was increased, as well as its percentage of total nitrogen.

In order to establish whether the latter effects were the results of the biological activity of the applied ribonucleic acid, the acid was inactivated before application. Part of the extracted ribonucleic acid solution was boiled for 5 min. with 0·5 *N* potassium hydroxide. The *p*H was adjusted as outlined previously, and the solution was applied to the acceptor trees in exactly the same manner as the unboiled solution of ribonucleic acid. As seen from Table 1 the boiling of ribonucleic acid annuls its effect completely. It has been shown[3] that uracil induces the synthesis of protein when the ratio of uracil to guanine is increased. The addition of inactivated ribonucleic acid supplies uracil to the leaves but does not change the ratio of uracil to guanine and possibly therefore no protein synthesis was induced. Hence it is probable that a specific configuration of the intact ribonucleic acid is necessary to induce protein synthesis in the acceptor tree after transmission.

In a previous communication[3] it was shown that uracil affects, via ribonucleic acid, the amino-acid composition of the leaves. This was now also found true for transmitted ribonucleic acid as shown in Table 2.

Table 2. THE EFFECT OF TRANSMITTED RIBONUCLEIC ACID UPON THE COMPOSITION OF THE LEAF PROTEIN OF NON-BEARING PEAR TREES

* Leaves from non-bearing (pear on pear) trees.
† Leaves from non-bearing trees which were treated with ribonucleic acid from bearing trees.

The values obtained for the amounts of the different amino-acids making up the leaf protein are greatly affected by the treatment. Especially the amount of *iso*leucine, of which only traces were found in the untreated leaves, was increased due to ribonucleic acid. Of special interest is the appearance of *nor*leucine and a quinoline derivative—kynurenine—which in certain animals is an oxidative product of L-tryptophan[5–7] and a precursor of nicotinic acid in plants[8]. The significance of the appearance of kynurenine will be discussed in a separate paper.

The above results demonstrated the possibility of transmitting ribonucleic acid in its 'native' state from one tree to another; the transmitted acid then causes certain changes in the synthetic activity of the acceptor tree. Hence one might consider whether there are not certain similarities between the effect of normal and viral ribonucleic acid, the 'normal' and 'abnormal' activities of a plant being often only a matter of degree.

Planting Distance and Number of Seedlings in Rice Cultivation

FOR early paddy a planting distance[1] of 6 in. × 6 in. using six seedlings[2] at each spot has been recommended. But this narrow row-spacing limits the use of interculture implements like rotary weeders, thereby affecting the economy of paddy cultivation. In order to find out if the row spacing could be increased without a detrimental effect on yield, and also to determine the corresponding number of seedlings to be planted at each spot, a field experiment was designed with rice variety *N*22, planted at 6 in. × 6 in., 8 in. × 4½ in. and 12 in. × 3 in., using

Table 1. Analysis of Variance

Least significant difference for interaction: Grain, 8·20; straw, 14·26

two, four and six seedlings. The nine treatment-combinations were replicated four times in split plot design, with an ultimate plot-size of 6 ft. × 9 ft. Crop was harvested on October 6, 1956, ten weeks after transplanting. Results of analysis of variance of yield and of grain and straw yields are represented in Tables 1 and 2 respectively.

Only interactions were found to be significant. From a comparison of italic figures in Table 2, it is evident that distance between rows can be increased without a deleterious effect on the yield of rain-fed early rice by a corresponding decrease in the number of seedlings planted at each spot—thereby also deriving benefit of a much lower seed-rate. In other words, at a given area for a clump of rice plants, the optimum number of seedlings planted at each spot is a function of, and directly proportional to, the shorter side of planting distance.

Apparent Requirement for Vitamin K of Rumen Strains of *Fusiformis nigrescens*

An organism producing coal-black colonies on blood agar has been isolated in numbers of 10^{4-5}/gm. from the rumen contents of six cows fed on kale, hay and concentrates or grass diets and from the rumens of two abbatoir-killed cows. It may therefore be a normal component of the flora of the bovine rumen.

The organism is a Gram-negative cocco-bacillus and a strict anaerobe, producing a black pigment and a foul odour from blood. The cells measure about 0·4 × 0·3–0·2μ, occurring singly or in pairs. Longer forms and chain formation were found at minimum concentrations of menaphthone. These characteristics suggest its identity with *Fusiformis nigrescens*[1]. It was grown on 10 per cent horse blood 'Lemco' agar in an atmosphere of 90 per cent hydrogen and 10 per cent carbon dioxide at 39° C. and was first isolated in association with an anaerogenic rumen strain of *Proteus*[2]. When grown in pure culture, *F. nigrescens* died out after giving rise to various atypical forms, for example, where growth occurred at isolated points on the plate; maximum growth did not coincide with points of maximum inoculation, or where growth occurred in the form of minute colourless colonies. Other workers[3] have remarked on the variability in growth of this organism. When *Proteus* was inoculated into blood plates showing atypical growth, or plates inoculated with *F. nigrescens* which did not show growth after incubation for one week, good growth of *F. nigrescens* with typical colony formation developed on further incubation; control atypical plates remained the same.

Attempts were made to determine the growth-promoting factor. Filtrates of *Proteus* grown under aerobic and anaerobic conditions were added to blood plates, but no consistent stimulation was obtained. Attempts to remove a possible growth-inhibiting substance in the medium by the addition of 0·1 per cent soluble starch, 0·03 per cent ethylene diamine tetra-acetic acid and urease were without effect. Chocolate agar and laked blood[3] also failed to influence the growth of the organism.

This difficulty in cultivating *F. nigrescens* is analogous in a number of ways to that existing in the culture of *Mycobacterium johnei* without *M. phlei*. The growth of certain strains of *M. johnei* is enhanced by the addition of vitamin K to the medium[4]. An autoclaved suspension of menaphthone in water was therefore added to a blood 'Lemco' agar plate to give a final concentration of 5γ/ml. Good growth was obtained after six days incubation and *F. nigrescens* has been subcultured serially on this medium. Moreover, menaphthone was able to revive atypically growing cultures in the same manner as *Proteus*. In liquid medium dense growth was obtained after three days incubation in 1 per cent blood 'Lemco' broth + 15γ/ml. menaphthone and also at ranges of menaphthone and menaphthone sodium bisulphite of 0·25–25γ/ml. after three days. No growth or very poor growth was obtained in 'Lemco' blood broth alone, and no growth was obtained in 'Lemco' broth containing a range of menaphthone concentrations.

Preliminary experiments suggest that this requirement for vitamin K by rumen strains of *F. nigrescens* is specific, and the inhibition of the growth of *F. nigrescens* by the natural antagonist of vitamin K, dicoumarin, is competitive. Thus, inhibition occurred when the amount of dicoumarin was equal to the amount of menaphthone added at a level of 0·25γ/ml., and 1·5 times the amount of menaphthone when the latter was added at 25γ/ml.; that is, approximately equal proportions of dicoumarin/menaphthone result in inhibition at both levels.

Many organisms, including *Proteus*, are known to synthesize vitamins of the K group[5], and synthesis by rumen micro-organisms supplies the requirements of the cow for this vitamin[6]. These preliminary experiments give an example of vitamin interdependence among micro-organisms in the rumen. A more detailed study of the nutrition of *F. nigrescens* and experiments to develop a microbiological assay technique for vitamin K with this organism are in progress.

Importance of Photoperiod and Temperature in inducing Diapause in the European Corn Borer, *Pyrausta nubilalis* (Hbn.)

The European corn borer was first found in Ontario in 1920[1] and, until recently, was primarily a single-generation species, producing one larval brood each summer and overwintering in diapause in the final larval instar. Beginning about 1941, a marked change in the seasonal history of the corn borer occurred. The numbers of larvæ completing development without diapause and giving rise to second-generation larvæ increased until it now constitutes a substantial part of the total borer population[2]. As one approach to an understanding of this divergence in seasonal history, we initiated a study on factors in diapause in the corn borer, including environment.

The larvæ used in this study were obtained from a laboratory culture of borers that were multivoltine at normal rearing temperatures. All larvæ in the culture were reared individually in one-dram shell vials containing a modification of Beck's[3] diet. Eight successive generations have been reared at 85° F. and approximately 70 per cent relative humidity without interruption by diapause and with no apparent reduction in vigour.

In an initial experiment, groups of newly hatched borers were reared at 45°, 55°, 65°, 75° or 85° F. to determine the effect of temperature on larval development and on the occurrence of diapause. The borers reared at 45° and 55° F. died in the second instar; those reared at 75° and 85° F. developed normally and pupated, whereas those reared at 65° F. entered a diapause. These results indicate that diapause in laboratory-reared borers can be induced by controlling the larval rearing temperature. An experiment in which larvæ in each of the five instars were reared at 65° F. for one instar and at 85° F. for the remaining instars showed that the low-temperature treatment is relatively ineffective in inducing diapause unless the treatment occurs in the fifth instar. Furthermore, fewer borers enter diapause if the larvæ have been more than one day in the fifth instar at the beginning of the low-temperature treatment.

In the foregoing experiments a photoperiod of 8·5 hr. light per day was used. Failure to induce diapause in comparable numbers of larvæ under continuous illumination at 65° F. turned our attention to the possible role of photoperiod in diapause induction. Groups of larvæ reared to the end of the fourth instar at 85° F. and constant light were transferred to 65° F., and a photoperiod of 0, 4, 8, 16, 20 or 24 hr. light per day until they had either pupated or entered diapause. The results of this experiment are compared with data for photoperiods of 8·5 and 9·5 hr. light per day, and are summarized in Table 1. The number of borers entering diapause at 65° F. increased with increasing light periods up to 9·5 hr. light per day; photoperiods of 16–24 hr. light per day were relatively ineffective. A similar experiment at 75° F., in which light periods of 0, 8, 16 and 24 hr. light per day were tested, induced diapause in no larvæ.

Table 1. Influence of Photoperiod, at 65° F., on Induction of Diapause in the European Corn Borer, *Pyrausta nubilalis* (Hbn.)

Hr. light per day	Initial No. of larvæ	Percentage mortality	Survivors entering diapause (per cent)
0	37	43	0
0	50	10	7
4	44	12	32
8	45	2	59
8·5	75	7	69
9·5	65	22	96
9·5	58	7	94
16	39	3	3
20	39	8	3
24	41	2	8
24	25	16	5

The stock used in these experiments, though multivoltine at normal rearing temperatures, thus has a facultative diapause. Furthermore, it is clear that temperature and photoperiod are factors of importance in the initiation of diapause in the borer.

Blackhead Toppling Disease of Bananas

Blackhead disease of bananas was described by Ashby[1] as occurring in Jamaica in 1915 and being caused by a nematode, identified by Cobb[2] as *Tylenchus similis* Cobb, now renamed *Radopholus similis*. It was not sufficiently serious on the Gros Michel variety in 1942 to be listed by Martyn[3] among the banana diseases of Jamaica.

Ever since Panama disease necessitated the replacement of the Gros Michel banana by a resistant variety in Jamaica, Lacatan bananas have been grown more and more extensively there, notably since the 1951 hurricane. Lacatan bananas have, however, recently been found highly susceptible to the old blackhead disease. This has been well demonstrated where an experimental acre plot of Gros Michel bananas on one estate is practically free of the disease whereas the Lacatan bananas of the same age, in the same field, are riddled with it.

The presence of blackhead disease has only been realized since high winds have uprooted a large number of banana plants without causing 'breakneck' of the pseudostems. Investigations have shown that the roots of such plants have been so extensively invaded by *Radopholus similis* that they have been killed by the entry of secondary organisms into the stele. Where infection is not very severe, plants may produce good grades of fruit, and the heaviest losses from toppling often occur in such circumstances. Present indications are that, where the disease is particularly severe, losses from toppling may not be so serious because the plants are backward in growth and bear light bunches. The roots of young suckers tend to be less heavily invaded than those of the parent plants and these healthier roots are able to assist in anchoring the parent. In the taller plants, bearing heavier fruit, this assistance is inadequate to prevent toppling.

Radopholus similis is a burrowing nematode which soon leaves tissue rotted by secondary organisms, with the result that examination of blackened roots and heads (corms) frequently yields remarkably few parasitic nematodes. To find *R. similis* readily in the banana plant it should be sought in two regions, namely, where purplish streak lesions (less than $\frac{1}{16}$ in. wide and often not more than $\frac{1}{4}$ in. long) occur on young roots and, also, at the junction of diseased and healthy tissue near the surface of the corm, which is seldom invaded to a depth of more than half an inch. Invaded tissue is isolated by the formation of wound cambium. Although able to confine the nematodes to the surface layers of the head in this way, the banana plant is unable to resist penetration into the comparatively loose-celled parenchyma of the root cortex, so that the nematodes readily enter as far as the endodermis, where secondary organisms gain access to the vascular system, resulting in death of the roots.

Leucocytozoon spp. in some Hertfordshire Birds

During the course of some work on the blood parasites of birds[1] (some of which has been or will shortly be published[2]) gametocytes of several species of *Leucocytozoon* were observed in the blood of seven species of birds. In the absence of reports of the incidence of this parasite in British birds since those of Seligman and Sambon[3] (in grouse), Woodcock[4] (in chaffinches and redpolls) and Coles[5] (in thrush, blackbird, jay, pigeon, starling, moorhen and "many others") it is thought that results from the present investigation (which took place between 1953 and 1955) might be of interest.

All the birds were shot or trapped near St. Albans, Hertfordshire, and thin films of their peripheral blood (stained with Giemsa's stain) were examined under a magnification of about 100 diameters for at least 10 min. The term 'adult' in Table 1 refers to all birds which had left the nest and were able to fly.

Details of the birds which were found to be infected are recorded in Table 1. No parasites were found in nine adult and four nestling song thrushes (*Turdus e. ericetorum* Turton), eight adult and one nestling starlings (*Sturnus v. vulgaris* L.), or seven adult house sparrows (*Passer d. domesticus* L.). (Species of which fewer than five individuals were examined are excluded from this list.)

Table 1. Incidence of *Leucocytozoon* spp. in some Hertfordshire Birds

Species of bird	Age group	No. examined	No. infected	Percentage infected
Rook (*Corvus f. frugilegus* L.)	Adult	52	8	15
	Nestling	25	0	0
Jackdaw (*C. monedula spermologus* Vieill.)	Adult	27	1	4
Blackbird (*Turdus m. merula* L.)	Adult	33	9	27
	Nestling	12	0	0
Wood pigeon (*Columba p. palumbus* L.)	Adult	12	2	17
	Nestling	1	0	0
Blue tit (*Parus caeruleus obscurus* Pražak)	Adult	5	1	20
Carrion crow (*Corvus c. corone* L.)	Adult	2	2	—
Tawny owl (*Strix aluco sylvatica* Shaw)	Adult	1	1	—

The species of *Leucocytozoon* found were identified as follows: *L. sakharoffi* Sambon 1908 in rook, jackdaw and carrion crow; *L. dubreuili* Mathis and Leger 1911 in blackbird; *L. marchouxi* Mathis and Leger 1910 in wood pigeon; *L. majoris* (Laveran 1902) in blue tit; and *L. danilewskyi* Ziemann 1898 in tawny owl. This last species was found inhabiting both round and elongated host cells in the blood, whereas all the other species were found in round cells only.

It is interesting to note that no nestling birds were found to be infected. Of the 52 adult rooks examined, 48 were known to be less than one year old (because they possessed a forwardly directed tuft of feathers at the base of the beak which is lost at the beginning of the second year[6]), and all the infected birds were among this group. This suggests that infection of British rooks (and probably other species) does not occur until either just before or after they leave the nest.

I wish to thank Prof. P. C. C. Garnham for his advice and interest throughout this work.

Influence of Parasitization on Form Determination in Aphids

Parasitization of the immature stages of some insects and Crustacea is known to result in structural abnormalities in the adults. Examples from insects are the production of 'intersexes' in certain Homoptera and Hymenoptera when parasitized by Strepsiptera[1], and of 'intercastes' of ants parasitized by nematodes[2]. Unparasitized aphids intermediate in structure between alate and apterous forms have been observed and described a number of times[3], and

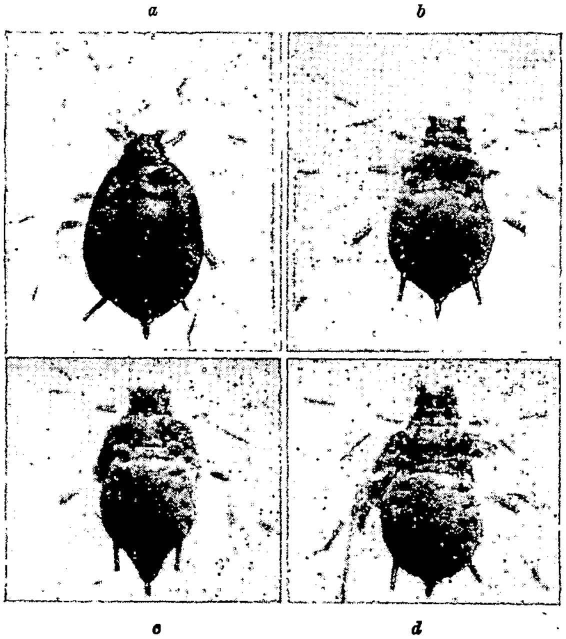

Fig. 1. Extent of suppression of alate structures in adult aphids by parasitization at different stages of development. These aphids were parasitized at (*a*) second instar; (*b* and *c*) early third instar; (*d*) late third instar

it has now been found that in *Aphis craccivora* Koch this kind of intermediate can be produced by parasitization of alatiform nymphs by the braconid wasp *Lysiphlebus testaceipes* (Cresson).

In a series of experiments, aphid nymphs which would normally have developed into alatæ were parasitized at various stages of their development, and the structural characters of the ensuing adults were observed. Until the third nymphal cutical is laid down there is no apparent structural difference between nymphs which will develop into alatæ or apteræ, and early instar alatiform nymphs were obtained by subjecting adult aphids to conditions which were known to result in the production of alatiform progeny. Adults of *A. craccivora* which had been kept for several days on cuttings of *Vicia faba* bearing only mature leaves were found to produce more than 90 per cent alatiform nymphs, whereas aphids kept on seedlings produced almost exclusively apteriform nymphs.

The extent to which alate structures were suppressed by parasitization depended upon the stage of development at which the aphids were parasitized. Aphids parasitized in the third and early fourth instars developed into intermediates in which the size of the wing pads and degree of differentiation of the thorax varied according to when they were parasitized; but they all had lateral ocelli and secondary sensoria on the antennæ, both of which are typically alate structures. Aphids parasitized in the third instar became adults without wing pads and having greatly reduced lateral ocelli and no antennal sensoria. Aphids parasitized in the first instar did not survive the fourth instar in which they had no alatiform structures and were indistinguishable from normal fourth instar apteriform nymphs except that they showed some degree of prothetely: in a number of them the form of the cauda was intermediate between those of the nymph and the adult, and they all had some typically adult pigmentation. The only apparent effect of parasitization on the structure of apteriform nymphs was in nymphs parasitized in the first instar which in the fourth instar had some adult structures.

The means by which interference with the determination of alate structure in aphids is effected is not known. Attempts to simulate the effects of parasitization by puncturing the aphids with a fine needle were unsuccessful, although severe burn injuries to parts of the abdomen of third instar nymphs did in a number of cases result in the aphids becoming intermediate between alatæ and apteræ. Ultimately form determination is probably due to the availability to the epidermal cells which produce the polymorphic structures of some substance or substances at optimum concentration at certain more-or-less critical times during development. Nutrition, which has been shown to influence form determination in a number of insects, is not likely to be involved here, as starvation of developing aphids, for example, by allowing them to develop on wilting plants, or removing them from the plants for considerable periods, merely results in smaller adults and does not cause a reversal of form. It seems more reasonable, in the light of present knowledge of the role of hormones in insect development, to suspect that the presence of the parasite causes interference with the hormone system of the nymphs. The occurrence in some parasitized aphids of prothetely, which can be caused by hormonal upsets[4], supports this, but experimental proof is lacking.

This work is being continued in the hope that it may throw some light on the mechanism of determination of form in aphids.

Balanus tulipiformis Ellis on the Atlantic Coast of France and an Unusual Situation for *B. amphitrite* Darwin

In June 1956, a stone carrying a large red barnacle was brought up by a trawler from a depth of about 25 m., between the mouth of the Adour and Cap Breton. The specimen was identified by Dr. J. P. Harding of the British Museum (Natural History) as *Balanus tulipiformis* Ellis. So far as can be ascertained, *B. tulipiformis* has not previously been reported from any part of the Atlantic coast of Europe. Its distribution is given by Darwin[1] as Sicily, Malta, Malaga (associated with *B. perforatus*) and Madeira. Gruvel[2] gives the same distribution. Nilsson-Cantell[3] adds one further habitat, Wasin (West Africa).

Further, the specimen, with a basal diameter of 50 mm., would appear to be the largest of the species so far recorded from any locality. Darwin gives the measurement of the largest specimen (from Malta) as 1·4 in. (about 35 mm.) in basal diameter, and adds that, usually, full-sized specimens are about $\frac{3}{4}$ in. (about 20 mm.) in basal diameter. Gruvel gives the basal diameter as 18 mm.

Since the discovery of this specimen, it has become apparent that the species is well established on the south-west coast of France.

There is a 'whistling' buoy outside the bay of Saint-Jean-de-Luz moored in 25 m. of water. Each year this buoy is taken up, usually in September, being immediately replaced by another. The buoy was examined for cirripeds in September 1956 and again in September 1957.

When the buoy was taken from the water in September 1956 there was a number of isolated *Balanus* scattered over the surface below the water-line. These included a score or more *B. tulipiformis*, some of which had a basal diameter of 35 mm. There was a much greater number of *B. perforatus* Bruguière, and there were a few of a third species, identified by Dr. Harding as *B. amphitrite* Darwin. In September 1957, 36 *B. tulipiformis* were counted on the buoy. They were concentrated on or near the junction of the tube with the floating part of the buoy, that is to say somewhat deeper in the water than the rounded part of the buoy on which they had mostly settled the year before. The basal diameters of the largest specimens were 40 mm. (2), 38 mm. (3), 37 mm. (3). These sizes were attained in a single year, the buoy having been in the water from September 8, 1956, until September 18, 1957. As in the previous year there was a far larger number of *B. perforatus*, but on this occasion only one *B. amphitrite* (juv.) was observed. There was also a quantity of *Lepas anatifera* L. This species had not been seen in the previous year.

The buoy is situated at least 25 km. from the area from which the first example of *B. tulipiformis* was obtained. From more or less that same area and depth—25 m. or more—the same trawler, in July 1957, brought up a very old anchor on which were fixed a number of *B. tulipiformis* of various sizes. On the anchor was found the outer shell of what appears to have been a *B. tulipiformis* of great size, with a basal diameter of more than 75 mm. Young specimens of this species have also been found on shells of *Ostrea rugosa* Gmelin taken from crayfish traps set in 30 m. of water, or deeper, off Saint-Jean-de-Luz.

The presence of *B. amphitrite* on the buoy in 1956 is worthy of note. In a recent study of the cirripeds on the north coast of Spain, E. Fischer-Piette and M. Prenant[4] have noted the presence of *B. amphitrite* in certain ports and estuaries and its absence in others. This is explained as due to the fact that, to establish itself, this species requires a certain amount of turbidity in the water and is not to be found where the water is very clear. In an earlier work on the distribution of the principal intertidal species on the north coast of Spain, Fischer-Piette[5] remarks that in the situations known to him he has found this species living only in ports, estuaries and lagoons, and never on the open coast. In a letter to me he has stated that, except on the hulls of ships, he has only seen the species "dans des milieux souillés ou confinés".

It is probable that, in the case of the *B. amphitrite* on the buoy, the condition of turbidity of the water at the time of settlement may have been satisfied. Although more than a kilometre from the nearest land, the buoy is in direct line with the entrance of the harbour of Saint-Jean-de-Luz in the estuary of the River Nivelle. After heavy rain, an area of turbidity can be seen to extend up to and beyond the buoy, and sometimes to remain visible for several days. One cannot, therefore, exclude the possibility that, at the time of settlement of the larvæ of *B. amphitrite*, there may have been sufficient turbidity in the water around the buoy to permit of their establishment. On the other hand, the buoy is well out in the open sea, 1,200 m. from the nearest land. So there is no question here of a confined space. As noted above, only one young specimen of *B. amphitrite* was found on the buoy in 1957.

My sincere thanks are due to Dr. J. P. Harding for his identifications and for his kind advice in the preparation of this communication. I also wish to acknowledge the assistance received from Prof. E. Fischer-Piette and Monsieur M. Prenant.

A Possible Ecologial Effect of Upwelling in a Submarine Canyon

During July–November 1956, an exploratory ecological survey along the south-west edge of the La Jolla submarine canyon was conducted over a sandy bottom using self-contained underwater breathing apparatus[1] diving techniques (for a chart of the region see Shepard and Emery[2]), and the following preliminary information may be of general interest.

There are sharp changes in the dominant species of animals as one swims toward the north-west along the canyon axis between the 27- to 37-m. contours. In the shoreward regions (area 1) abundant populations of the sea-pen, *Stylatula elongata*, and the sea-star, *Astropecten californicus*, exist. Abruptly the community changes and is almost entirely *Astropecten* for about 50 m. (area 2). Continuing farther (area 3), brittle stars, *Ophiura lütkeni*, are found almost exclusively. On the broad, sandy continental shelf to the north *Ophiura* are not found until a depth of 47–50 m. is reached; *Astropecten* here occurs at 40–23 m. and *Stylatula* at 23–10 m. Boundaries between communities on the shelf appear to run parallel to the depth contours; at the canyon they run across the contours.

100–150 m. traverses were swum near the 30-m. contour along the edge of the canyon through the regions mentioned above. Centrally within these regions counts of animals were made in areas chosen at random by quadrats cast down blindly. Table 1 presents the marked differences which were found.

Table 1

Animal	Size of quadrat (m.^{2})	No. of individuals in each sample	Individuals (per m.^{2})
Area 1			
Astropecten	1	0, 0, 0, 0, 0, 0, 0, 2, 0, 3, 3	1
Stylatula	1	2, 1, 2, 1, 0, 0, 3, 5, 7, 6, 0	2
Ophiura	1	0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,	0
Area 2			
Astropecten	1	1, 6, 4, 10, 2, 1	4
Stylatula	1	0, 0, 0, 0, 0, 0	0
Ophiura	1	0, 0, 0, 0, 0, 0	0
Area 3			
Astropecten	1	0, 0, 0, ½, 0, 0, 0, 0, 0, 0	0
Stylatula	(three observed during a 50-m. swim)		0
Ophiura	0·05	4, 5, 4, 3, 2, 0, 3, 0, 5, 3, 0, 4	60

The areas on the canyon rim are not characterized by any large differences in substrate, depth and temperature. We have, however, while on the bottom in area 3, observed water currents coming from the direction of the canyon travelling up slopes as steep as 26°. Current velocities are variable both in magnitude and direction; but this is characteristic of near-shore currents in southern California. Velocity measurements, determined by timing the progress of a cloud of permanganate solution for 1 m., yielded vertical components as great as 45 cm./min. upwards. Studies of area 1 have as yet failed to give evidence of upwelling; this difference may be an important factor influencing the distributions discussed above. The commercially harvested kelp beds of *Macrocystis pyrifera* just south of area 3 may also be affected by the upwelling.

Tides, internal waves, and northerly currents could contribute to the upwelling; the biological data suggest that northerly currents may play an important part. Ophiuran populations occurring at 50 m. depth on the shelf and at 30 m. in the canyon allow the possibility of a water mass common to both places. Currents from the north at the 50 m. depth would run into the south wall of the canyon below area 3 and may upwell and flow across this region. Area 1 and possibly area 2, however, below 27 m. are protected from northerly currents by the shoal opposite wall of the canyon.

We are grateful for criticism and assistance to Prof. D. L. Fox and to Dr. E. W. Fager. The work was supported by the George A. Bisbee Donation and a Rockefeller Foundation donation for research in marine biology.

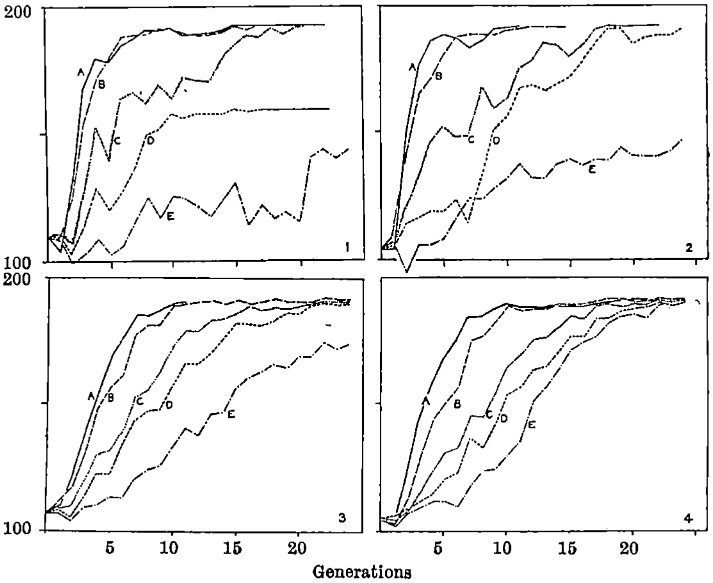
Monte Carlo Analyses of Genetic Models

AUTOMATIC digital electronic computers, such as the SILLIAC, have several features which are of use in simulation of genetic systems. These are the ability to form sets of pseudo-random numbers[1], the ability to perform the operations of logical summation, equivalence, etc., and particularly the ability to perform a sequence of operations repeatedly at high speeds. A programme[2] has been written for the SILLIAC which simulates the action of selection on a population segregating for six loci. The programme has been run for complete dominance, equal effects at all loci, and no interactions between loci. The number of progeny was set at 100, and of parents at 50. Mating was at random. The initial population was set to contain the gametic types listed in binary notation in Table 1.



Figs. 1–4. Rates of advance under selection calculated by the SILLIAC. In each figure there are five lines representing different degrees of recombination. Figs. 1–2 are at high intensity of selection, small population size. Figs. 3–4 are at low intensity of selection, large population size

Table 1. FREQUENCIES OF GAMETIC TYPES IN PARENT POPULATIONS

Location

a	*b*	*c*	*d*	*e*	*f*	Frequency
0	0	1	0	0	1	0·11111
0	0	1	0	1	0	,,
0	0	1	1	0	0	,,
0	1	0	0	0	1	,,
0	1	0	0	1	0	,,
0	1	0	1	0	0	,,
1	0	0	0	0	1	,,
1	0	0	0	1	0	,,
1	0	0	1	0	0	,,

The values of recombination between the six loci were set at the values given in Table 2.

Table 2. RECOMBINATION VALUES

Location

a	*b*	*c*	*d*	*e*	*f*	
0·5	0·5	0·5	0·5	0·5		*A*
0·25	0·25	0·5	0·25	0·25		*B*
0·05	0·05	0·5	0·05	0·05		*C*
0·025	0·025	0·5	0·025	0·025		*D*
0·005	0·005	0·5	0·005	0·005		*E*

The programme therefore simulates conditions of recombination from complete independence (*A*), to tight linkage in two chromosomes, each containing three loci. Two runs were made at each set of recombination values, starting at different points in the set of pseudo-random numbers. The results are shown in Figs. 3 and 4.

As would be expected on general grounds, and from the analyses of Wright, Haldane and Fisher, there is a decrease in the rate of advance with increasing tightness of linkage. None of the runs showed any periods of no advance as were found by Mather[3] and used by him as the basis for the polygene concept. The programme was run again, changing the number of progeny to 40, of parents to 4 (that is, approximating the values of Mather's experiment). The results are shown in Figs. 1 and 2.

In these runs a more marked retardation of the rate of advance by increasing tightness of linkage was found. This is particularly the case in the runs at recombination values of 0·005, where distinct lags occurred in the advance under selection which are analogous to those found by Mather[3] in his second selection line which is illustrated in Fig. 5.

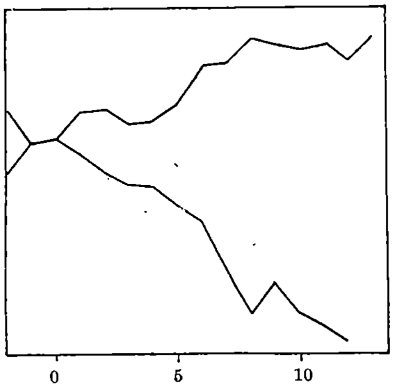


Fig. 5. Rates of advance under selection in *Drosophila*, from Mather, ref. 3

These runs indicate that any effects of linkage on the amount of variability present in a population will be slight at recombination values greater than 0·005 in populations of reasonable size. In small populations, the effects of linkage of this intensity are sufficiently great to produce qualitative changes in the curve of advance under selection, considerably reducing the efficiency of selection.

The above analyses are sufficiently encouraging to justify writing further programmes for Monte Carlo analyses of genetic systems. Three are being written covering (*a*) single loci, multiple populations with migration, (*b*) several loci, with variation of dominance, interactions, linkage, and number of chromosomes, and (*c*) several loci, no linkage, several phenotypes, environmental variation, non-random mating. Monte Carlo analyses can never be a substitute for complete mathematical simplifications. They can, however, be regarded as complementary to the present incomplete mathematical solutions, and provide an easily used tool for those geneticists, such as myself, who cannot otherwise add to the mathematical theory of natural selection.

An Experimental Design for Three Factors at Three Levels

IN an experiment with three factors at three levels each, the experimenter may be willing to sacrifice information on certain components of the two-factor interactions and to ignore the three-factor interactions completely except as an estimate of error[1]. A possibly useful experimental design for this purpose is detailed below.

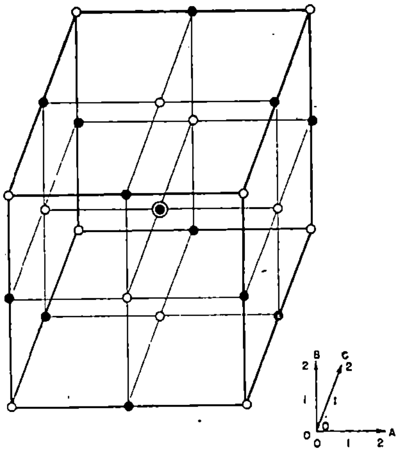

Fig. 1. The 3^3 factorial design and the cuboctahedron plus centre point. ○, ● + ⊙, 3^3 factorial; ●, cuboctahedron; ⊙, centre point

The experimental arrangement permits independent estimation of and tests of significance on both the 'linear' and 'quadratic' components of the main effects and on the 'linear × linear' components of the three two-factor interactions. As the basic experimental design requires only 16 observations, it can be used in 'mixed series' experiments with other factors at two or four levels each in partial replication of the whole (De Baun, R. M., unpublished). Moreover, quadruplicate replication of one experimental combination permits an estimate of true experimental error. The experimental design and appropriate orthogonal polynomials are detailed in Table 1. We may compare the power of estimation in this design to that of the 27 point 3^3 factorial design in single replication, by taking the variances of the several effects corrected by the ratio of the numbers of observations in each experiment. These variances relative to those of the 3^3 factorial design are: linear effects 1·333, quadratic effects 0·888 and linear times linear interaction effects 1·185. We thus gain information on the quadratic effects while sustaining an information loss on the linear effects and their interactions.

The experimental design cannot be further blocked independently of the previously cited effects. However, omission of a (111) point permits blocking into three blocks of 5 with the block contrasts partially confounded with the quadratic effects.

The basic experimental design can be seen to be a symmetrical fraction of the 3^3 factorial, as is shown in Fig. 1. Geometrically, the design may be viewed as a cuboctahedron in single replication with quadruplicate observations at the centre.

Table 1. EXPERIMENTAL COMBINATIONS AND ORTHOGONAL POLYNOMIALS

Observation	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
A level	0	2	0	2	1	1	1	1	0	0	2	2	1	1	1	1
B level	0	0	2	2	0	2	0	2	1	1	1	1	1	1	1	1
C level	1	1	1	1	0	0	2	2	0	2	0	2	1	1	1	1
A effect	−1	+1	−1	+1	0	0	0	0	−1	−1	+1	+1	0	0	0	0
A^2 effect	+1	+1	+1	+1	−1	−1	−1	−1	+1	+1	+1	+1	−1	−1	−1	−1
B effect	−1	−1	+1	+1	−1	+1	−1	+1	0	0	0	0	0	0	0	0
B^2 effect	+1	+1	+1	+1	+1	+1	+1	+1	−1	−1	−1	−1	−1	−1	−1	−1
AB effect	+1	−1	−1	+1	0	0	0	0	0	0	0	0	0	0	0	0

The analysis of the variance breaks down to nine degrees of freedom for treatments (three linear, three quadratic and three interaction), three degrees of freedom for lack of fit, that is, higher-order interactions and three degrees of freedom for true error, if properly randomized.

Vowel Recognition in Clipped Speech

It would be a great advantage if computers used for translation from one language into another could be provided with voice-operated input equipment. This development, however, depends on the isolation of information-bearing factors in speech, that is, a distinction among different sounds produced by a speaker and an identification of the same sound produced by different speakers.

In the course of work on speech-input devices for a translating machine, clipped speech was examined for the possible extraction of information-bearing factors. Since it is reported to be intelligible[1–4] while carrying information solely in the temporal pattern of zero-crossings, an apparatus was constructed to analyse the fine structure of the zero-crossings. The apparatus consisted of a magnetic tape player followed by amplifying and clipping circuits. The output was taken through a variable gate to a scaler so that the number of pulses in short intervals of time (of the order of 0·02 sec.) could be counted. The width of the gate was measured by passing generator pulses through it and counting them by means of the scaler. This arrangement, with routine precautions, allowed the number of pulses and time to be determined to an accuracy of about 1 per cent.

The first elementary sounds to be analysed were the vowels, because of their stability[5–8] and comparatively easy aural intelligibility. As a result of the experiment it was found that the plots of the number of pulses versus gate-width for the various vowels spoken by different persons were perfect straight lines. The slopes of these lines increased regularly from the vowel *i* (as in 'meet') to the vowel *a* (as in 'father'). Furthermore, the slopes were found to be reproducible within the limits of error of the apparatus. The vowels were thus recognizable singly as well as in combinations. Some of these results are shown in Figs. 1 and 2.

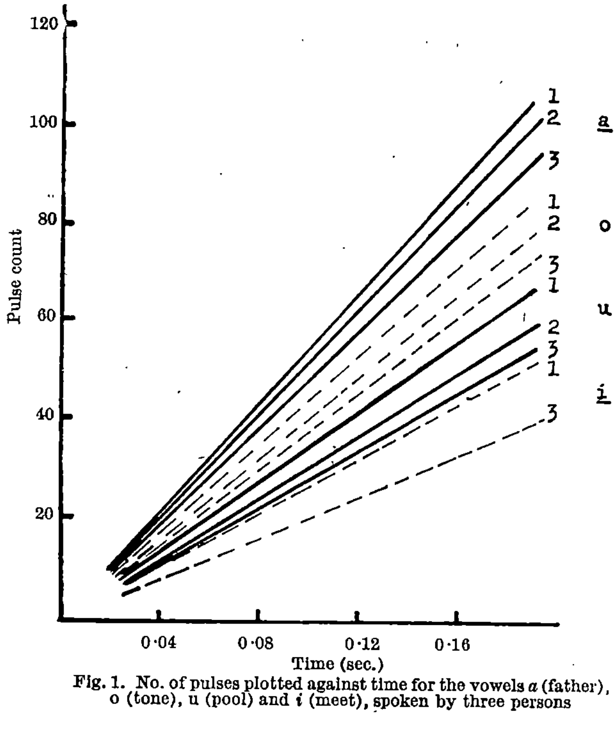

Fig. 1. No. of pulses plotted against time for the vowels *a* (father), o (tone), u (pool) and *i* (meet), spoken by three persons

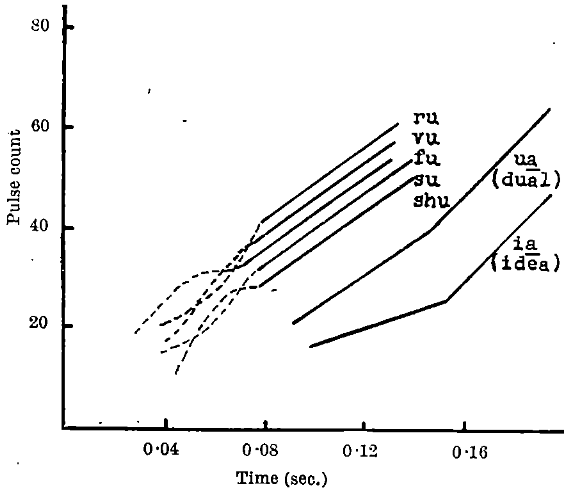

Fig. 2. Characteristic slopes of vowels in combination

Counts per sec.

	a	o	u	*i*
Voice 1	558	450	350	283
,, 2	533	417	317	—
,, 3	491	384	292	218

The constancy of pulse count per second for the various vowels throws some light on the particular feature by which clipped speech conveys information. Since vowels are made up of recurring trains of pulses (and yet they cannot be copied by pulses taken from a generator), it seems obvious that they carry information by: (1) the number of pulses in the interval of fundamental frequency and (2) the width-modulation of these pulses. It is interesting that the number of width-modulated pulses in the fundamental interval may be as small as two to three, as in the case of the vowel *i*.

Further work is being done on width-modulation within the fundamental period, and detailed results of the present study will appear elsewhere.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, January 20

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Mr. J. W. Birch: "The Economic Geography of the Isle of Man".

British Computer Society (at York Hall, Caxton Hall, Westminster, London, S.W.1), at 6.15 p.m.—Dr. N. Levin: "The Physical Principles of Xerography".

Institute of Metal Finishing (at Northampton Polytechnic, St. John Street, London, E.C.1), at 6.15 p.m.—Mr. A. McL. Aitken: "Some Properties and Applications of Chemically Reduced Nickel Coatings".

Royal Institute of Chemistry, London Section (at Enfield Technical College, Queensway, Ponders End), at 7.30 p.m.—Dr. S. F. Birch: "Petroleum Chemicals".

Monday, January 20—Tuesday, January 21

Society of Chemical Industry, Pesticides Group (in collaboration with the Industrial Pest Control Association, at 14 Belgrave Square, London, S.W.1), at 10 a.m. daily—Symposium on "Pests of Stored Products".

Tuesday, January 21

British Nuclear Energy Conference (at The Hoare Memorial Hall, Church House, Westminster, London, S.W.1), at 9.30 a.m.—Symposium on "Nuclear Energy".

Institution of Civil Engineers (at Great George Street, London, S.W.1), at 5.30 p.m.—Mr. J. F. Greinig, Mr. R. W. Horseman and Mr. A. N. Kinkead: "The Design and Construction of the Foundations and Pressure Shell of the 8 ft. by 8 ft. High-Speed Wind Tunnel of the R.A.E., Bedford".

Institution of Electrical Engineers, Measurement and Control Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. G. F. Tagg: Informal lecture on "The Effect of Modern Industrial Requirements on Electrical Instrument Design".

Royal Aeronautical Society (at 4 Hamilton Place, London, W.1), at 7 p.m.—Mr. P. J. Duncton and Mr. T. F. R. George: "Environments and Environmental Testing".

Wednesday, January 22

Geological Society of London (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. C. H. Holland: "The Ludlovian and Downtonian Rocks of the Knighton District, Radnorshire"; Mr. F. M. Broadhurst: "A New Species of *Anthraconaia*, and a Study of Palæoecology in the Coal Measures of the Oldham Area, Lancashire".

Royal Statistical Society (at the London School of Economics, Houghton Street, London, W.C.2), at 5.15 p.m.—Mr. G. S. Watson: "On Chi-Square Goodness-of-Fit Tests for Continuous Distributions".

Eugenics Society (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Dr. G. C. L. Bertram: "Eugenics in the Age of Crowding".*

Institute of Fuel (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p.m.—Dr. D. W. Gillings and Mr. W. Lawson: "The Shatter Strength of Cokes from High-Volatile Coals: Use of Plastometer Measurements on Blends for Test-Oven Experiments".*

Institution of Electrical Engineers, Radio and Telecommunication Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. E. Esping: "Special Problems of Broadcasting in Sweden".

Institute of Physics, Education Group (at 47 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. B. C. Brookes: "Presenting Science in Physics Text Books".

Institution of Mechanical Engineers, Applied Mechanics Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6.45 p.m. —Discussion on "The Measurement of Noise and Vibration".

British Psychological Society, Medical Section (at the Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 8.30 p.m.—Mr. D. Russell Davis: "Clinical Problems and Experimental Researches" (Chairman's Address).

Thursday, January 23

University College, London (in the Physiology Theatre, Gower Street, London, W.C.1), at 5 p.m.—Dr. E. Lester Smith: "The Biochemical Functions of Vitamin B_{12}".*

University College, London (in the Anatomy Theatre, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. R. E. D. Bishop: "Applied Mechanics in Engineering"* (Inaugural Lecture).

Oil and Colour Chemists' Association (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Mr. J. H. W. Turner, Mr. S. E. Hanson and Mr. S. G. Kemp: "The Function of Aluminium Complexes as Structure Modifers in Paints".

Royal Aeronautical Society (at 4 Hamilton Place, London, W.1), at 7 p.m.—Mr. L. H. Bedford: "Guidance and Control".

Friday, January 24

British Glaciological Society (at the Geography School, 341 Bristol Road, Birmingham), at 5.30 p.m.—Mr. J. W. Glen: "The Cambridge Austerdalsbre Expedition 1955–57".

Saturday, January 25

Biochemical Society (at the Glaxo Laboratories, Greenford, Middlesex), at 11.15 a.m.– Scientific Papers.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Principal of the Institute of Agriculture, Moulton—Chief Education Officer, County Education Offices, Northampton (January 25).

Research Assistant (qualified biochemist with some research experience) to Sir Rodolph Peters—The Secretary, Institute of Animal Physiology, Babraham, Cambridge (January 25).

Laboratory Steward (familiar with the maintenance and preparation of general equipment and materials for chemistry and physics)—The Registrar, North Oxfordshire Technical College and School of Art, 51 The Green, Banbury, Oxon (January 25).

Lecturer in Mathematics—The Secretary of University Court, The University, Glasgow (January 31).

Lecturer (preferably with special interests in high frequency techniques or in servomechanisms) in Electrical Engineering—The Registrar, The Manchester College of Science and Technology, Manchester 1 (January 31).

Lecturers in Inorganic Chemistry and in Physical Chemistry —The Registrar, The Manchester College of Science and Technology, Manchester 1 (January 31).

Senior Lecturer in Electrical Engineering at Singapore Polytechnic—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (January 31).

Senior Research Fellow (graduate in mining, physics, mathematics or engineering, with postgraduate experience, preferably in the field of applied mechanics) in the Postgraduate School of Mining, to undertake a study of the mechanics of rock fracture in mining processes—The Registrar, The University, Sheffield (January 31).

Assistant Physicist (graduate) in the Physics Department, Coventry Radiotherapy Centre—The Secretary, Group 20 H.M.C., Coventry and Warwickshire Hospital, Coventry (February 1).

Lecturer (Grade I or Grade II) in the Department of Agriculture, University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 3).

Lecturer (with special qualifications in physical chemistry) in the Department of Chemistry—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (February 8).

Analyst (with B.Sc. degree, preferably with honours in organic chemistry or equivalent and an interest in biochemistry and animal nutrition) in the Nutrition Research Laboratory, Department of Agriculture, Glenfield, New South Wales, Australia—The Agent-General for New South Wales, 56 Strand, London, W.C.2 (February 12).

Assistant Lecturer or Lecturer in the Department of Applied Mathematics—The Registrar, The University, Liverpool (February 14).

Reader in Geology at Bedford College—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 14).

Imperial Chemical Industries Research Fellows in Biochemistry, Chemistry, Engineering, Pharmacology, Physics, Chemical Technology or Chemical Engineering—The Secretary, The University, Edinburgh (February 15).

Lecturer in Zoology at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 15).

Senior Lecturer (with high academic qualifications and/or professional qualifications and some teaching experience) in Chemical Engineering at Neath Technical College—The Director of Education, County Hall, Cardiff (February 17).

Lecturer or Assistant Lecturer (preferably with research interest in some aspect of taxonomy) in Botany at the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 25).

Babcock and Wilcox Research Fellow in Nuclear Engineering—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (February 28).

Challis Chair of Philosophy at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (February 28).

Courtaulds' Fellows (2) (with a good honours degree in physics, chemistry or chemical engineering) for research in textile chemistry—The Registrar, The Manchester College of Science and Technology, Manchester 1 (February 28).

Lecturer (graduate with an interest in electronics and preferably a knowledge of experimental stress analysis) in the Department of Textile Industries—The Registrar, The Manchester College of Science and Technology, Manchester 1 (March 1).

Leverhulme Postgraduate Fellows (3), two in the Faculty of Science and one in the Faculty of Engineering—The Registrar, The University, Liverpool (March 1).

Research Fellow for independent research—The Registrar (Room 22, O.R.B.), The University, Reading (March 17).

Assistant (Grade B) to teach Chemistry with some Physics or Mathematics—The Principal, North-West Kent College of Technology, Miskin Road, Dartford.

Electronic Engineer, for the construction of electronic apparatus with special application to biological material—The Secretary, Institute of Ophthalmology, Judd Street, London, W.C.1.

Electronics Technical Assistant (capable of maintaining and servicing existing equipment and assisting with the design and production of new electronic apparatus) in the Interdepartmental Workshop of the Royal Free Hospital School of Medicine—The Secretary, Royal Free Hospital School of Medicine, 8 Hunter Street, London, W.C.1.

Lecturer, Assistant Professor, Postdoctorate Fellow, and a Research Assistant in the Department of Physics—Head of the Department of Physics, University of British Columbia, Vancouver B.C., Canada.

Master to teach Mathematics throughout the School to University Scholarship standard—The Headmaster, The Perse School, Cambridge.

Mathematicians and Physicists (with a good honours degree in mathematics or physics and preferably experience in hydro-dynamics and modern computing techniques), for work on theoretical reactor physics and transport theory—The Recruitment Officer (1002Z/34), Atomic Energy Research Establishment, Harwell, Didcot, Berks.

Research Assistant in the Computing Machine Laboratory—The Registrar, The University, Manchester 13.

Scientific Officer (with a first- or second-class honours degree in physics or natural sciences or equivalent qualification), to undertake research in the physical and mechanical properties of explosives and to apply the data to a study of problems arising in weapon design—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berks, quoting Ref. 1659/34.

Senior and Junior Research Fellows (with a first- or second-class honours degree in an appropriate subject and evidence of a very high standard of ability in research) at Government Scientific Establishments—The Civil Service Commission, Scientific Branch, 30 Old Burlington Street, London, W.1, quoting S.4798/58.

Senior Laboratory Technician (male), to be responsible for the Laboratories (Chemistry, Physics, Biology), other Laboratory Staff and equipment and stock—The Principal, North-West Kent College of Technology, Miskin Road, Dartford.

Senior Lecturer in High Polymer Technology—The Principal, Welsh College of Advanced Technology, Cathay's Park, Cardiff.

Senior Lecturer (preferably with an active interest in research in some branch of applied mathematics) in Mathematics—The Clerk to the Governors, Northern Polytechnic, Holloway, London, N.7.

Visiting Lecturer in Mathematics—Prof.. A. D. Wallace, Tulane University, New Orleans, La., U.S.A.

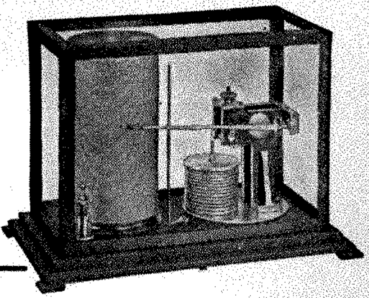
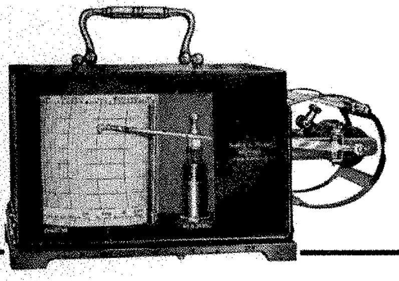
MICRO-BAROGRAPH

This recorder has a very open scale in which 2½ linear inches equal 1″ barometric pressure. Essential for weather forecasting, barometric pressure studies and survey work. Supplied with 24-hour or 7-day revolution clock and charts in inches, millimetres and millibars. Prompt delivery.





THERMOGRAPH

This is a highly sensitive bimetallic coil instrument having a low-drum weekly clock, exposed element and "gate" suspension pen arm. Supplied complete with 6″ setting Thermometer, a year's supply of charts and ink. Prompt delivery.

ALSO BRASS CASE BAROMETERS · SURVEYING ANEROID BAROMETERS MERCURIAL BAROMETERS · HYGROMETERS · HYGROGRAPHS · STANDARD THERMOMETERS · ANEMOMETERS · WIND SPEED AND DIRECTION INDICATORS · RAIN GAUGES · GAS MEASURING INSTRUMENTS, etc., etc.

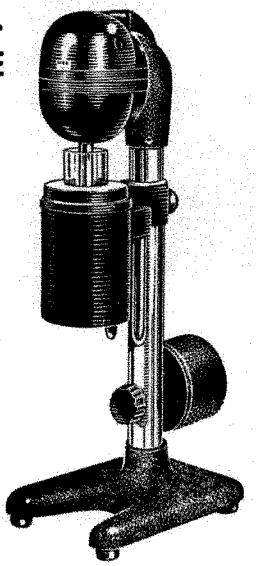
MSE Homogeniser

and MACERATOR

FOR 1 c.c. to 100 c.c. WITH TEMPERATURE CONTROL FACILITY



The most versatile laboratory mixer made. It takes four different types and sizes of container enabling it to handle quantities from 100 c.c. down to 1 c.c. Speed is infinitely variable up to 14,000 r.p.m. The housing for the 100 c.c. and 10 c.c. containers can be filled with dry ice or other convenient coolant, providing effective counter-action to the temperature rise normally met in high-speed blending.

LECTURES AND COURSES

UNIVERSITY OF BIRMINGHAM

FACULTY OF SCIENCE

M.SC. COURSE IN RADIOACTIVITY

A course of lectures and practical work in general radioactivity leading to the degree of M.Sc. by examination, is available in the Department of Physics. The course is suitable for honours graduates in physics or related subjects wishing to obtain special experience in radioactive techniques including radiochemistry.

M.SC. COURSE IN REACTOR PHYSICS AND TECHNOLOGY

A course of lectures and practical work in Reactor Physics and Technology leading to the degree of M.Sc. by examination, is available in the Faculty of Science. The course is suitable for graduates with a good degree in pure or applied science (normally physics, metallurgy, mechanical engineering or chemical engineering). Some introductory lectures and tutorial assistance will be provided to bring entrants to the necessary standard of knowledge in relevant branches of both physics and engineering.

These courses will last for one academic year, the fee is £81. Graduates wishing to be considered for the Advanced Course Studentships of the Department of Scientific and Industrial Research, must apply to the Registrar, University of Birmingham, before February 1, 1958. In certain cases a maintenance allowance with fees may be awarded by the University. Application for admission to the courses starting in October, 1958, and requests for further informaion, should be made as soon as possible to the Registrar.

UNIVERSITY OF BIRMINGHAM

DEPARTMENT OF MATHEMATICAL PHYSICS

GRADUATE SCHOOL IN MATHEMATICAL PHYSICS

The Graduate School in Mathematical Physics is intended for graduates holding a good honours degree in mathematics with subsidiary physics, who propose to take up work involving the practical application of mathematics to physical and similar problems. Candidates who are successful in the examination at the end of the course, will be awarded a Diploma in Mathematical Physics. The course lasts for one session (October to July). The fee is £58.

Application for admission to the course, starting in October, 1958, and requests for further information, should be made as soon as possible to the Registrar, University of Birmingham. In the case of candidates wishing to be considered for the advanced Course Studentships of the Department of Scientific and Industrial Research, it is desirable that application be made to the Registrar before February 15, 1958. In certain cases, a maintenance allowance with fees may be awarded by the university.

IMPERIAL COLLEGE, CHEMICAL ENGINEERING Department: Course of 16 lectures on High Pressure Technology will be given from January 28, 1958.—Full particulars from the Registrar, Imperial College, London, S.W.7.

OFFICIAL APPOINTMENTS

BRITISH COLUMBIA RESEARCH COUNCIL

OPERATIONAL RESEARCH

The British Columbia Research Council has a vacancy for an experienced Operational Research Scientist. Applicants should be not more than 35 years of age and should be actively engaged in Operational Research. The Council's laboratories are located on the campus of the University of British Columbia. The Council is engaged in industrial research and works very closely with the University.

Applicants wishing further information regarding the position should write to Dr. G. M. Shrum, Director, British Columbia Research Council, Vancouver 8, B.C.

UNIVERSITY OF GLASGOW

LECTURESHIP IN MATHEMATICS

Applications are invited for a Lectureship in Mathematics. Salary scale: £900 to £1,650. Initial salary according to experience and qualifications. F.S.S.U. and family allowance benefits.

Applications (eight copies) should be lodged, not later than January 31, 1958, with the undersigned, from whom further particulars may be obtained.

ROBT T. HUTCHESON,
Secretary of University Court.

COMMONWEALTH of AUSTRALIA

COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION

DIVISION OF INDUSTRIAL CHEMISTRY

APPOINTMENT NO. 590/658 OF RESEARCH SPECTROSCOPISTS

The Organization's Division of Industrial Chemistry is at present seeking to appoint two Research Spectroscopists. The Division is located in modern and well equipped laboratories at Fisherman's Bend, Melbourne. The spectroscopy group is part of the Chemical Physics Section which includes 30 Research Officers and 22 Technical and Workshops staff. The appointees will be required to work on the following Research topics: (1) Development of the field of atomic absorption spectroscopy and its application to theoretical and applied problems, and (2) Experimental and theoretical studies of electronic and vibrational spectra of co-ordination compounds in relation to structure. Applicants should possess a university degree of Master of Science or Doctor of Philosophy in chemistry or physics, preferably with some research experience in the general field of spectroscopy. Successful applicants will be members of the Spectroscopy group, which has facilities for vacuum ultra-violet, visible and near ultra-violet, infra-red, Raman and echelle spectroscopy. Dependent upon qualifications and experience, commencing salary will be determined within the salary ranges of Research Officer or Senior Research Officer, £A.1,313 to £A.1,938 per annum, or £A.2,048 to £A.2,323 per annum. Salary for a female appointee will be £A.167 less than the corresponding male rates quoted. The appointment will be conditional upon a satisfactory medical examination and the appointee will be required to contribute to and eligible to receive benefits from either the Commonwealth Superannuation Fund or the Commonwealth Provident Account.

Applications, quoting Appointment No. 590/658 and stating full name, place, date and year of birth, nationality, marital state, present employment, particulars of qualifications and experience, and of war service, if any, accompanied by copies of not more than four testimonials and the names and addresses of three professional referees should reach the undersigned, from whom further particulars may be obtained, by February 28, 1958.

A. SHAVITSKY,
Chief Scientific Liaison Officer.
Australian Scientific Liaison Office,
Africa House, Kingsway, London, W.C.2.

UNIVERSITY COLLEGE

IBADAN, NIGERIA

FACULTY OF MEDICINE

Applications are invited for post of Senior Technician in the Department of Anatomy. Experience in museum and histological techniques desired. Applicants should be A.I.M.L.T. or possess equivalent qualification and experience. Appointment, to commence as soon as possible, for three years in first instance. Salary £900 by £25 to £950 per annum. Entry point determined by qualifications and experience. Allowance for up to three children, £50 per annum per child resident in Nigeria, £100 per annum per child resident elsewhere. Outfit allowance £60. Passages for appointee, wife and up to three children under 11 years, on appointment, overseas leave and termination. Part-furnished accommodation at rent not exceeding 7.7 per cent of salary. Basic tour 15 to 18 months. Pension scheme.

Detailed applications (eight copies), naming three referees, by February 12, 1958, to Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 from whom further particulars may be obtained.

D.S.I.R. WATER POLLUTION RESEARCH Laboratory, Stevenage, Herts, require Scientific Officer (Physicist, Physical Chemist or Chemical Engineer), preferably with good mathematical ability, to undertake (a) laboratory studies and theoretical consideration of settlement of flocculating and non-flocculating solid particles in quiescent and flowing aqueous media, and (b) laboratory and pilot plant studies of influence of design of sedimentation tanks on flow of liquid through such tanks and on settlement of suspended particles. Qualifications, first- or second-class honours degree in physics, chemistry or chemical engineering. Salary £595 to £1,050. Starting pay according to postgraduate experience and National Service. Women's pay slightly less. Equal pay scheme. Normal promotion to Principal Scientific Officer in mid-thirties (£1,370 to £1,950). Five-day week. Houses and flats to rent available to staff of laboratory.—Forms from Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.3/8A. Closing date: February 15, 1958.

WHITE FISH AUTHORITY

APPOINTMENT OF TRAINEE AREA OFFICER/FREEZING INSPECTOR

The White Fish Authority invite applicat from men not over 30 years of age for app ment as Trainee Area Officer/Freezing Inspe Area Officers/Freezing Inspectors are the r sentatives of the Authority at the fishing p and the duties of the post will include the spection of fresh fish intended for freezing, th spection of the freezing processes and the sto and treatment of the fish after freezing. A high dard of education is essential and the posses of a university degree in science with experi in the application of quality standards to would be advantageous. Salary in trainee g £700 by £50 to £850 per annum, with prospec promotion to Area Officer/Freezing Insp grade rising to £1,150 per annum. A contribu Superannuation Scheme is in operation.

Applications, stating age, education, quali tions, and giving details of experience and and present appointments, and also the name two referees, should be sent to the Secret Solicitor, Tilbury House, Petty France, S.W.1 as to reach him not later than January 31, 1

OXFORDSHIRE EDUCATION COMMITTEE

NORTH OXFORDSHIRE TECHNICAL COLLEGE AND SCHOOL OF ART

(Principal: N. A. Pratt, A.T.D.)

Applications invited for the post of Lab tory Steward (new post). Applicants should familiar with the maintenance and preparatio general equipment and materials for chem and physics. Additional experience of ap science or biology laboratories would be an vantage. Salary scale: £460 to £550 per ann Duties will commence as soon as possible.

Application forms obtainable from the R trar at the College, 51 The Green, Banbury O to whom they should be returned within weeks of the appearance of this advertisemen

A. R. CHORLTON, M.
Director of Education.

County Offices,
Oxford.

CHELSEA COLLEGE OF SCIEN AND TECHNOLOGY

MANRESA ROAD, S.W.3

DEPARTMENT OF CHEMISTRY

Applications are invited for the post of Lect with special qualifications in physical chemi Salary scale: Men, £1,200 to £1,350; Wo £1,062 17s. to £1,350 plus London allowanc £36 or £48 according to age.

Further particulars and form of applica may be obtained from the Clerk to the Gover by whom applications should be received not than February 8, 1958.

SHEFFIELD REGIONAL HOSPIT BOARD

SHEFFIELD NO. 4 H.M.C.

RADIOTHERAPY CENTRE

ASSISTANT PHYSICIST

Applications are invited for an appointmen Assistant Physicist in the Physics Departmen the Sheffield National Centre for Radiother Candidates should possess a good honours de in physics. The appointment may be into ei the Senior Grade or Basic Grade according qualifications and experience. Previous experi of hospital physics not necessary for appointn in basic grade. Salary according to Wh Council Scales.

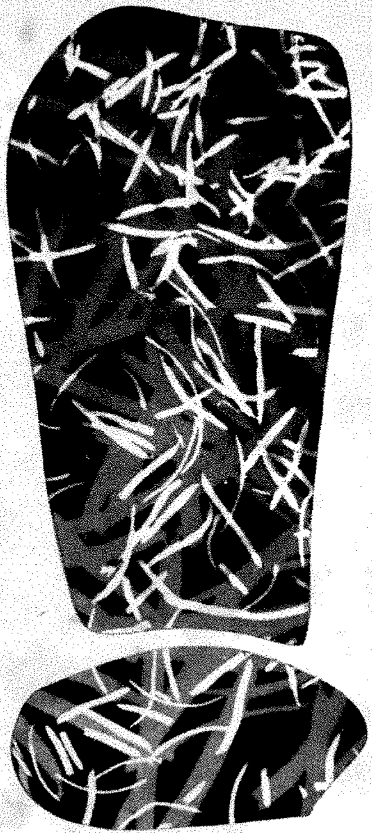
Applications, with names of at least referees, should be sent to the Secretary, " Br Cross," Tree Root Walk, Sheffield, 10, wi fourteen days of the appearance of this adver ment. Further particulars of the post may obtained on application to the Secretary.

LONDON SCHOOL OF HYGIEN AND TROPICAL MEDICINE

UNIVERSITY OF LONDON

Applications are invited from graduates physics, chemistry or engineering for the new of Occupational Hygienist in the Rockefeller of Occupational Health at the School. Du call for development of research in studying working environment in relation to disease. Sa in the Lecturers' scale of £1,100 to £1,600 F.S.S.U., child and London allowances.

Applications, supported by the names of referees, should be sent by February 14, 1958 the Dean, London School of Hygiene and Trop Medicine, Keppel Street, Gower Street, W. from whom further particulars may be obtai



Only very occasionally does a new material appear that has a widespread potential throughout industry.

Here, though, is just such a product — a unique material that deserves your fullest understanding.

Refrasil

is the name given to a lightweight fibrous silica material, of very fine diameter, which is capable of withstanding continuously temperatures in the order of 1,000°C, or for short periods, even above. It has outstanding thermal insulating characteristics at elevated temperatures, as well as being an excellent high temperature electrical insulator. Like fused silica it has a high resistance to thermal shock and to chemical attack from acids.
It is available as batt, felted wool, cloth, tape, sleeving, bulk fibre, cord, and yarn.
There are many other things well worth your knowing about Refrasil; we have incorporated them all in a brochure which we would like to send you.

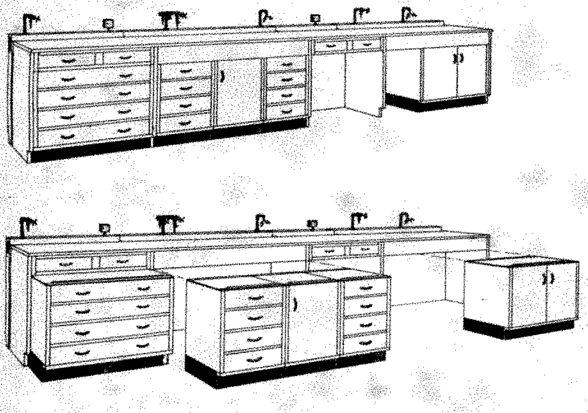
a NEW range of LABORATORY METAL FURNITURE

AND PREFABRICATED SERVICE RACKS



The *flexibility, economy* and *general usefulness* of UNIT furniture are advantages which cannot be disregarded. We offer standard benches of modern design and construction, with removable units, in metal and wood; and standard service racks which will connect up to supplies (electricity, gas, water, steam, etc.) provided at any one point in the Laboratory. May we tell you more about them?

MUFFLE FURNACES

FOR GENERAL PURPOSES
MAXIMUM TEMPERATURE 1000°C. ENTIRELY SELF-CONTAINED

- Modern, clean appearance with built-in control equipment.
- Cases made of asbestolite panels which ensure maximum resistance to corrosion and present smooth external surfaces.
- High quality wire-wound elements, external to the muffles and hence protected from fumes and gases arising inside the furnace during operation.
- Uniform temperature and low power consumption.
- All furnaces protected by a temperature fuse.
- Removable panel permits easy access for renewal of heating elements in the event of failure.

Send for catalogue No. 558A giving full details of our complete range of laboratory furnaces.

CASELLA LONDON

A NEW INSTRUMENT FOR SAMPLING AIRBORNE DUST–

THE HEXHLET

This instrument enables a bulk sample of the 'respirable' fraction of a dust cloud to be collected for subsequent chemical analysis. It employs a horizontal elutriator consisting of a number of flat horizontal ducts through which air is drawn at a constant velocity, such that particles above about 7μ will settle out before reaching the end. The air flow is maintained constant by means of a 'critical orifice'. Suction is provided by an air ejector. The respirable fraction of the dust is collected in a Soxhlet filter thimble which will hold up to 2 grammes of dust before its resistance becomes too high.

THE INSTRUMENT IS NOW IN PRODUCTION

ORGANIC ELECTRODE PROCESSES

by

Milton J. Allen

Director of the Physical Research Laboratories,
CIBA Pharmaceutical Products Inc., Summit, N.J.

The author has devoted his whole career to organic electro-chemical investigations involving methods of preparation of organic compounds utilising oxidation or reduction techniques. His studies have also encompassed the mechanisms and kinetics of organic electrode processes. Mr. Allen's purpose in writing his book is to give organic chemists the fundamental information to start investigatory work.

HARNESSING NUCLEAR FUSION

In replying on November 11 to a question in the House of Commons, the Paymaster-General, speaking for the Government, said that the experimental apparatus known as ZETA at the Atomic Energy Research Establishment, Harwell, was operating successfully, and discharges through heavy hydrogen were giving very high temperatures, accompanied by discharges of neutrons, believed to be due to thermonuclear reactions. It is appropriate that the first detailed account of this work should appear in *Nature*, where it will be read by scientists all over the world (see p. 217 of this issue).

Ever since the possibility of nuclear fission was realized, it was understood that a converse process of fusion of atomic nuclei was possible and would yield a vast amount of energy. This possibility became a fact with the invention of the hydrogen bomb. All the time, however, scientists in many countries were endeavouring to learn more about the mechanism of the reaction with the view of controlling this immense explosive force. A carefully considered account, by one of the Harwell scientists, of the theory involved was published in *Nature* of May 4, 1957, p. 886; this demonstrated the very stringent physical conditions which control of such processes must entail. Although it is generally recognized that we are continually witnessing the results of thermonuclear reactions—for they are believed to be the source of the heat and light given out by the Sun—their production and control in the laboratory present problems hitherto unparalleled.

The communications from British and American scientists appearing in this issue of *Nature* demonstrate that the first steps in this great task have been successfully taken. Teams of scientists at Harwell and Aldermaston have obtained results which led to the brief announcement made in the House of Commons on November 11. American scientists, working on slightly different lines, have also contributed their results, and it is heartening to read the tribute they pay to the Harwell scientists.

Bearing in mind the scientific importance and wide interest of the work already done, the lag between the Government's brief statement and the present publication of British and American results suggests that difficulties other than those of the laboratory have been met. The work was being done, perhaps inevitably in view of its complexity, under government auspices, in the two countries, and was subject to security restrictions. There seems to have been considerable exchange of information between the scientists directly concerned; but it is regrettable that security measures should have been invoked in such a quest, the significance of which for military purposes would not appear to be greater than that of innumerable scientific investigations in progress in various laboratories in both countries. Only those with full knowledge of the situation can give a final answer to this question.

However, the announcement of the successful control of the thermonuclear reaction has now been made, and all the scientists and others concerned are to be congratulated on their magnificent achievement.

Under the stress of military needs during the Second World War, great efforts were concentrated on the production of the atom bomb, leading to the preparation of fissile material of various kinds; the problem of converting this weapon to the production of energy for peaceful purposes was, for the time being, in the background. But with the end of open warfare, its utilization for the production of useful power became an urgent problem. The culmination of this effort was seen in the opening by H.M. The Queen in 1956 of Calder Hall power station, the first in the world to be solely dependent on atomic energy as a source of power. But the use of fissile material for this purpose, though a triumph of scientific and engineering skill, brought its own difficulties in the economic and other fields, for the initial cost of atomic fuel is high and it is a scarce commodity. Atomic energy power stations and the conventional power stations were seen to be complementary rather than competitive. Now we have the possibility of utilizing another 'atomic' fuel, of wonderful potentiality and world-wide occurrence, though whether it becomes the basis of the generation of electrical power, or means are found of making direct use of it as a source of energy, only the future will show. Meanwhile the control of nuclear fusion will be welcomed both as a great advance in science and as a factor of tremendous importance for the future, bringing vast stores of energy into the service of man for his use in the amelioration of his conditions.

In 1831, Michael Faraday discovered electromagnetic induction. His apparatus was of the simplest kind, consisting of a ring of iron on which two coils of wire insulated with "twine and calico" were wound, and a compass needle as detector. The experiment was not a chance affair, for his thoughts had turned repeatedly to the subject, and he had tried some experiments, but without success. Then he hit upon the correct sequence of events, and the experiment succeeded. Electricity had been generated in one simple circuit by making and breaking another simple circuit. From that experiment the electrical industry was born—the electrical age was initiated; and although its growth was at first slow, it now dominates the industrial world.

The new work on thermonuclear reactions is at present a laboratory experiment, albeit with most complex and costly equipment and even the risk of dangerous irradiation; it is clearly a first step, even as Faraday's experiment was. Life on the Earth has always depended on nuclear reactions in the Sun, and now it seems that man is learning to reproduce those reactions in the laboratory. Are we witnessing the birth of a new age—that of the utilization of man-made thermonuclear reactions ?

ENIGMATIC EDDINGTON

The Development and Meaning of Eddington's 'Fundamental Theory'

Including a Compilation from Eddington's Unpublished Manuscripts. By Dr. Noel B. Slater. Pp. xii+300. (Cambridge: At the University Press, 1957.) 40*s*. net.

EDDINGTON regarded physics as the structural knowledge of measures of an external world of objects that can be indicated but the intrinsic nature of which is not discoverable. Fundamental physics was for him the part concerned with properties of measures simply as operations, independently of what they operate on. He claimed to have discovered that fundamental physics in this sense comprises all the general laws of Nature, including the evaluation of all the constants involved. His book, "Fundamental Theory" (Cambridge 1946), was the final account of this work. The manuscript was not quite complete when he died in 1944, but was printed as he had left it, under the editorship of the late Sir Edmund Whittaker (who included one of Eddington's published papers on the intended subject of the missing last chapter).

Large parts of five or six earlier drafts had been preserved by Eddington, and Dr. N. B. Slater has collated these in the present book. After summaries of the main sections of "Fundamental Theory", Dr. Slater gives notes on the various drafts and extensive quotations wherever he considers that they contain a significant variant of an argument or material omitted from the final version. He provides a bibliography of writings on the subject that have been of assistance in preparing the book, and a useful list of the symbols employed by Eddington. He has also noted an error in a statistical argument of Eddington's that calls for one or two amendments in the evaluation of certain constants. His task has been extremely onerous, all the more so because the material reached him piecemeal in the course of the work. Clearly, he has exercised the utmost thoroughness, and the plan he has followed is almost certainly the one making for greatest conciseness. Dr. Slater is not to be blamed for the one regrettable feature of the presentation, the smallness of the type used for all quotations from Eddington.

Most physicists would go some way with Eddington in recognizing that their results are not so much properties of an external world as properties of their own operations upon such a world. A number would be glad to be able to go further. Each major conclusion as Eddington describes it in general terms appeals to them as possessing a high degree of plausibility and, if valid, as being profoundly illuminating. Yet they find insuperable difficulty in seeing very much connexion between any such conclusion and the detailed arguments and calculations that purport to establish it. A few physicists are, indeed, prepared to follow Eddington through separate sections of the work but without being satisfied as to the connexions between the sections. So far as I am aware, however, no physicist professes to understand the arguments of "Fundamental Theory" sufficiently thoroughly to be able to assert or deny that it provides a continuous chain of reasoning.

Were Eddington's work acceptable, it would of course be one of the very great advances in scientific thought. The new book might have led to a better understanding of the work had the available material shown how Eddington proceeded from an early stage to build up his final intricate structure. As Dr. Slater remarks, however, almost all the material at his disposal had been intended as a final version when it was written. One cannot, therefore, see much hope that it will help substantially to resolve the enigma of "Fundamental Theory".

The new material, together with Dr. Slater's commentaries, does make clearer than before what Eddington was trying to achieve. Also it shows that Eddington was wonderfully confident that he had achieved it. One cannot help thinking that he has at least indicated the general character of probable developments in physical theory. Such developments may ultimately come from some completely independent approach, or they may come from work like that of E. W. Bastin and C. W. Kilmister that is probably to some extent inspired by Eddington. But one would hazard the view that they are now scarcely likely to flow directly from Eddington's own treatment. For until acceptable conclusions have been reached by other means, it will probably be impossible to know how far Eddington relied upon his astonishing power of intuition. Nevertheless, Eddington's thought never lost its quality of greatness, even when it was most enigmatic, and we must be grateful to Dr. Slater and the publishers for this additional record of it. W. H. McCREA

HYDROGRAPHY

Hydrography of the Faroe–Shetland Channel, 1927–1952

By Dr. John B. Tait. (Scottish Home Department. Marine Research, 1957, No. 2.) Pp. ix+309. (Edinburgh and London: H.M. Stationery Office, 1957.) 105*s*. net.

FISHERY scientists have good reason to believe that changes in ocean currents and water circulation have an important bearing on variations in local stocks of fish and migration of fish shoals. For the whole of north-west Europe it is important to have a good knowledge of the varying balance between Arctic and Atlantic influences, and for the North Sea itself we must understand the varying influence of oceanic water which mixes with coastal water and flows from north to south across the herring fishing grounds. The first essential is to have measurements of what has taken place, and the most promising method known so far is to make regular surveys of the changing temperature and salinity of the water. The Faroe–Shetland Channel is a particularly informative area because a large proportion of the Atlantic water that warms the northern North Sea and the Arctic Ocean passes through it.

Dr. Tait's large monograph gives a detailed presentation of the vertical distribution of temperature and salinity along two roughly parallel cross-sections from the Faroe Islands to the Shetland Islands and from the Faroe Bank to the Butt of Lewis. On twenty-two occasions between 1927 and 1952 observations were made along both lines, and on a further twenty-five they were made along one or the other. Every now and then other lines were worked. The monograph gives diagrams showing the distribution of temperature and salinity in the vertical plane for every line of observations, and the observations themselves are listed in Appendix 2. It also gives the computed transport of water across each line assuming geostrophic flow and the existence of little or no current at the depth of the 35 parts per 1,000 isohaline. These assumptions are the best that can be made until it is feasible to carry out a very large programme of deep-current measurements, and they are supported by good general agreement between conclusions based on the two lines 120 miles apart, and by a few current measurements described in Appendix 1.

The work reveals large seasonal and long-term variations in the north-eastward transport of water, and opens up large and fascinating fields of research into the energy exchanges and hydrodynamical processes that cause them and into their effect on the complex hydrographic conditions and biology of the area. Linked with the main problem there is much information about the different types of water that are encountered there and practical conclusions as to their origin and formation. Enormous numbers of observations have been made with great care under difficult conditions, and this thorough and detailed study is a work of great value. It is prefaced by a good historical introduction, and it will itself be the foundation of much future work as well as serving present needs. G. E. R. Deacon

PREHISTORIC DENMARK

Denmark Before the Vikings

By Dr. Ole Klindt-Jensen. (Ancient Peoples and Places.) Pp. 212 (73 plates). (London: Thames and Hudson, Ltd., 1957.) 21*s*. net.

Denmark is a small country, but it has bred noted archæologists. As long ago as 1836 Christian Thomsen of the National Museum suggested the well-known triple subdivision of human history into the ages of Stone, Bronze and Iron. Later the names of Worsaae and Sophus Müller became world renowned. Denmark is rich in prehistoric remains and much exploration work has been done there, but no short, satisfactory account of the prehistory of the country has been published for very many years.

The new volume on Denmark by Dr. O. Klindt-Jensen, who is the curator at the National Museum in Copenhagen, is therefore very welcome. After a brief introduction there is a chapter headed "The Palæolithic". But while the term Palæolithic is not entirely inaccurate since some of the earliest cultures found in the country do, like that of Hamburg, overlap with the end of Magdalenian times, there is nothing in these northern regions to compare with the rich upper Palæolithic cultures of France and northern Spain with their wealth of industries in stone and bone and their superb art, both in the prehistoric homes and on the walls of caves. The industries of these northern cultures are at first simple, but there soon appear others belonging to the so-called point cultures which stretched westwards from as far away as Poland, where they occur below some ancient dunes. Later the classic Mesolithic cultures are represented at Maglemosean sites and in the Kitchen Middens. Actually the earliest manifestation of the former (Maglemose) culture is perhaps best seen in Britain at Star Carr, but in Denmark there are many sites and much exploration has taken place. It may be added that digging a late Mesolithic (Kitchen Midden) site is no fun—the fine white dust penetrates everywhere and everything. Denmark is particularly rich in Neolithic remains of all kinds; not least there is a magnificent series of Megalithic monuments. The author's account of these is necessarily brief, but gives a good picture of the situation. Chapters on the Bronze Age up to the Dark Ages follow, and there is a concluding chapter on the prehistoric landscape. Following some notes and a short bibliography there come the plates—no less than 73, occupying 48 full pages. These are well chosen and well illustrate the text.

Doubtless the specialist in one or more of the periods covered will complain that too much has had to be left out. But the ordinary reader will congratulate the general editor of the series, Dr. Glyn Daniel, on having persuaded Dr. Klindt-Jensen to undertake the work, and the author himself for having produced such an excellent little volume. M. C. Burkitt

THE BIOCHEMICAL LESION

Biochemical Disorders in Human Disease

Edited by Prof. R. H. S. Thompson and Prof. E. J. King. Pp. xiv+843. (London: J. and A. Churchill, Ltd.; New York: Academic Press, Inc., 1957.) 90*s*.

The enormous strides made by biochemistry during the past half-century and the ever-increasing application of biochemical concepts, as well as biochemical techniques, to the study of disease, have made important additions to the points of view from which disease can be surveyed, described and examined. From the cellular, we have advanced to the molecular level, and we can now think both of the anatomical or histological lesion and the underlying, more fundamental, 'biochemical lesion'. This convenient term, which we owe to Sir Rudolph Peters, is not actually used by the editors in the preface of this book, but it is implicit in what they say of their aims and lines of approach, and is indeed employed by contributors.

The object of the editors in planning the book was, for the benefit of both physicians and biochemists, to "assemble, relate, and interpret the known facts concerning the biochemical disorders that underlie or are associated with human disease"; the method was to ask each of a number of acknowledged experts to "describe . . . how the various diseases of any given organic system are dependent on biochemical disorders and to indicate the trends of biochemical work now in progress . . .". It can be said at once that the method has proved admirably adapted to a laudable aim. The editors and their fellow-contributors have succeeded in producing an exceedingly valuable addition to medico-biochemical literature and one which, I suspect, is likely to prove the prototype of the 'text-book of medicine' for the next generation.

Each author has been left free to interpret the editors' general directive in his own way, and as a result there is a considerable variety of treatment. This does not necessarily reflect differences in personal outlook, for the subjects are not equally 'advanced' from the biochemical point of view. In every case, however, the interpretation has clearly been that involved in the title of the book and in that of this review. In the past there has been too much emphasis on the function of biochemistry applied to medicine as a provider of diagnostic and prognostic tools, too little emphasis on its use in describing and explaining the nature and development of the disease processes ; yet the latter, which indeed includes, and is a logical extension of, the former, is by far the more important function of 'clinical chemistry' or 'chemical pathology'. In these chapters the diagnostic aids are discussed fully and extremely clearly, not as ends in themselves, nor as helping the physician to tie an appropriate label on his individual patients, but as the means of investigating the fundamental abnormalities whether considered as a general state covered by the label or as they afflict the individual. This is an essentially modern approach, well calculated to lead to a real understanding of disease and, through that, to therapy which can be adjusted rationally to the changing needs of a particular case.

The arrangement of the book is logical in relation to its general theme and it is a remarkable tribute to contributors and editors alike that the various chapters, written by different authors and each a review capable of standing alone, cover the ground fully, connectedly, yet without unnecessary overlapping. Twenty chapters deal with the diseases of the major organs (gastrointestinal tract, liver, kidney, pancreas, major endocrine glands, muscle), with disease groups not referable to particular organs (anæmias, hypertension, etc.) and with suitably grouped metabolic disorders (diseases of nutrition, porphyrias, lipoidosis and the like). Such an arrangement, probably the best for the clinician, means that a single biochemical topic such as acid-base equilibrium may be treated in several chapters by several authors and from various points of view. This is no disadvantage but is, indeed, one of the stimulating features of the book.

One ventures to predict that "Thompson and King" will become a classic, read and studied by senior medical undergraduates, by clinicians who wish to acquire understanding of their work, and by biochemists who, professionally or through interest, are concerned in the application of their science to the study of disease. C. P. STEWART

MECHANISM IN BEHAVIOUR

Behavior Mechanisms in Monkeys

By Heinrich Klüver. Second impression. Pp. xvii+387. (Chicago, Ill.: University of Chicago Press ; London : Cambridge University Press, 1957.) 49*s*. net.

THE study of the mechanisms underlying the activity of the central nervous system has claimed the attention of workers engaged in disciplines as far removed as, for example, psychology and electronic engineering, and it is therefore not surprising that there should be marked differences of emphasis and approach. Thus, of recent years, attention has been focused on mechanisms as they exist at the level of the individual cell, on the way in which neurones influence each other's activity, and on the part played by chemical processes in the specification and patterning of cerebral structure. Concurrently, and from quite a different point of view, mathematicians and communication engineers have been prompted to suggest that many problems of cerebral organization and function can best be treated on a statistical basis and to formulate hypotheses incorporating the established concepts of information theory and conditional probability to replace older views concerning the relationship between stimulus and response. To be fruitful, such advances in knowledge and thinking must be constantly applied to what is known about the reactions of the organism as a whole, and it is therefore particularly timely that Prof. Klüver's classic monograph "Behavior Mechanisms in Monkeys", which has been out of print for many years, has now been re-issued.

Prof. Klüver interprets the mechanism of behaviour in phenomenological terms, and his analysis is based on a study of those "general modes of reaction" from which it is possible "to predict the way an animal is going to react to a specific stimulus". He does not concern himself with the neural processes which underlie behaviour, but stresses, in his opening chapters, that little progress can be made in the investigation of cerebral function at the physiological level in the absence of firmly established experimental data concerning the overt factors governing the reactions of the individual to its environment. It is to this end that his monograph is directed.

The major portion of the book is devoted to a description and analysis of problems "selected chiefly because of their possible significance for neurophysiology". Experimental results are reported in considerable detail and fall into two groups. The first of these deals with investigations into the features of the stimulus situation to which the monkey responds. Variations of the 'pulling-in technique', which has since been extensively applied in experimental psychology, are used for determining the equivalence or non-equivalence of stimuli in the performance of discriminations involving weight, visual appearance and sound. The findings show an incidence of response to the relational aspects of the experimental situation which is consistently high over a wide range of cues ; but there are occasions, particularly in the case of some visual discriminations, in which the animal responds to absolute sensory criteria. The second group of experiments deals in a similar way with such behavioural capacities as visual and tactual acuity, handedness and the ability to use common objects as tools.

Prof. Klüver ends with a thorough and critical analysis of his findings. He concludes that to account for the persistence of certain forms of discriminative behaviour in the face of marked changes in the environment, it is necessary to postulate the presence of some component which is identifiable throughout the range of experimental situations ; but any definition of the property so abstracted as "an element which the stimuli have objectively in common" is unacceptable. Similarly, since the "response to relations" is not invariant, the unmodified concept of 'generalization' as a basic mechanism must be regarded as an over-simplification unless the individual characteristics of each stimulus situation are taken into account.

This book, which first appeared in 1933, is aimed at the serious student of behaviour rather than at the casual reader, and those unfamiliar with the extensive literature cited may have difficulty in following some of the arguments. Later developments are referred to in a new preface, but many of the original issues raised by Prof. Klüver still remain unresolved and it is gratifying that his monograph is once again readily available to a new generation of workers in the field of behavioural research.

J. T. EAYRS

CONTROLLED RELEASE OF THERMONUCLEAR ENERGY

PRODUCTION OF HIGH TEMPERATURES AND NUCLEAR REACTIONS IN A GAS DISCHARGE

By Dr. P. C. THONEMANN, E. P. BUTT, R. CARRUTHERS, Dr. A. N. DELLIS, D. W. FRY,
Dr. A. GIBSON, G. N. HARDING, D. J. LEES, R. W. P. McWHIRTER, R. S. PEASE,
Dr. S. A. RAMSDEN and S. WARD
Atomic Energy Research Establishment, Harwell

Introduction

THE basic conditions which must be established before a thermonuclear reactor is possible are, first, the containment of a high-temperature gas so that it is isolated from the walls of the surrounding vessel, and second, the attainment of temperatures sufficiently high for nuclear reactions to take place between the light elements. These two conditions are interdependent. Poor containment results in energy losses so large that gas temperatures much exceeding 10^6 °K. are unattainable.

The experimental apparatus described was designed to study the containment of ionized hydrogen (or deuterium) by the magnetic field associated with the current flowing in the gas and to reach temperatures sufficiently high for nuclear reactions to be detectable using deuterium. This apparatus, known as ZETA, was built at the Atomic Energy Research Establishment, Harwell.

The principles underlying the containment of a high-temperature gas by means of the 'pinch effect' have been discussed by a number of authors[1-3].

The constricted gas discharge formed by passing a high current through a low-pressure gas, while isolating the gas from the tube walls for short periods of time, rapidly develops instabilities and distortions which lead to bombardment of the walls by electrons and positive ions. The consequent cooling and recombination make it impossible to maintain high temperatures except for a transient period[4-8]. These instabilities can be suppressed by the combination of an axial magnetic field parallel to the direction of the discharge current and by the fields produced by eddy currents induced in the surrounding metal walls when the current channel changes its position.

Theoretical studies of discharge stability in the presence of an axial magnetic field have been published[9-12], together with experimental evidence for stability in a straight discharge tube[13].

The preliminary results reported in this article show that relatively long-time stability can be achieved in a toroidal metal-walled tube. The neutron yield and the kinetic ion temperatures have been measured over a limited range of conditions. The nuclear reaction-rates observed are not inconsistent with those expected from a thermonuclear process.

Apparatus

ZETA is a ring-shaped discharge tube of aluminium, 1-m. bore and 3-m. mean diameter, containing gas at low pressure. The gas, usually at a pressure of about 10^{-4} mm. of mercury, is made weakly conducting by a radio-frequency discharge. The toroidal ionized gas plasma forms the secondary of a large iron-cored pulse transformer. A condenser bank, storing up to a maximum of 5×10^6 joules, is discharged into the primary of the transformer, and produces a unidirectional current pulse in the gas up to a maximum of 200,000 amp. The current pulse in the gas lasts for about 4 msec. and is repeated every 10 sec. A steady axial magnetic field is generated by current-carrying coils wound on the torus. This field can be varied from zero to 400 gauss.

Fig. 1 shows the discharge tube assembled with the transformer. A vacuum spectrograph can be seen connected to the torus body.

Electrical Characteristics

Typical current and voltage oscillograms are shown in Fig. 2. The top trace is the 'voltage per turn' measured by a loop around the iron core enclosed by the discharge tube. The length of the discharge path is approximately 1,000 cm. so that the initial electric field at the boundary of the ionized gas is about 2 V. per cm. The primary winding is short-circuited when the voltage per turn is zero, thus preventing the charge on the condensers reversing. The second trace shows the current flowing in the gas, which persists for about 2 msec. after the transformer primary is short-circuited.

As the current decreases the plasma expands until it reaches the walls. It is then cooled. A sudden increase in resistance accompanies this process and the consequent increase in $|dI/dt|$ produces a severe voltage transient which may rise to tens of kilovolts. Destructive voltage transients of this type are

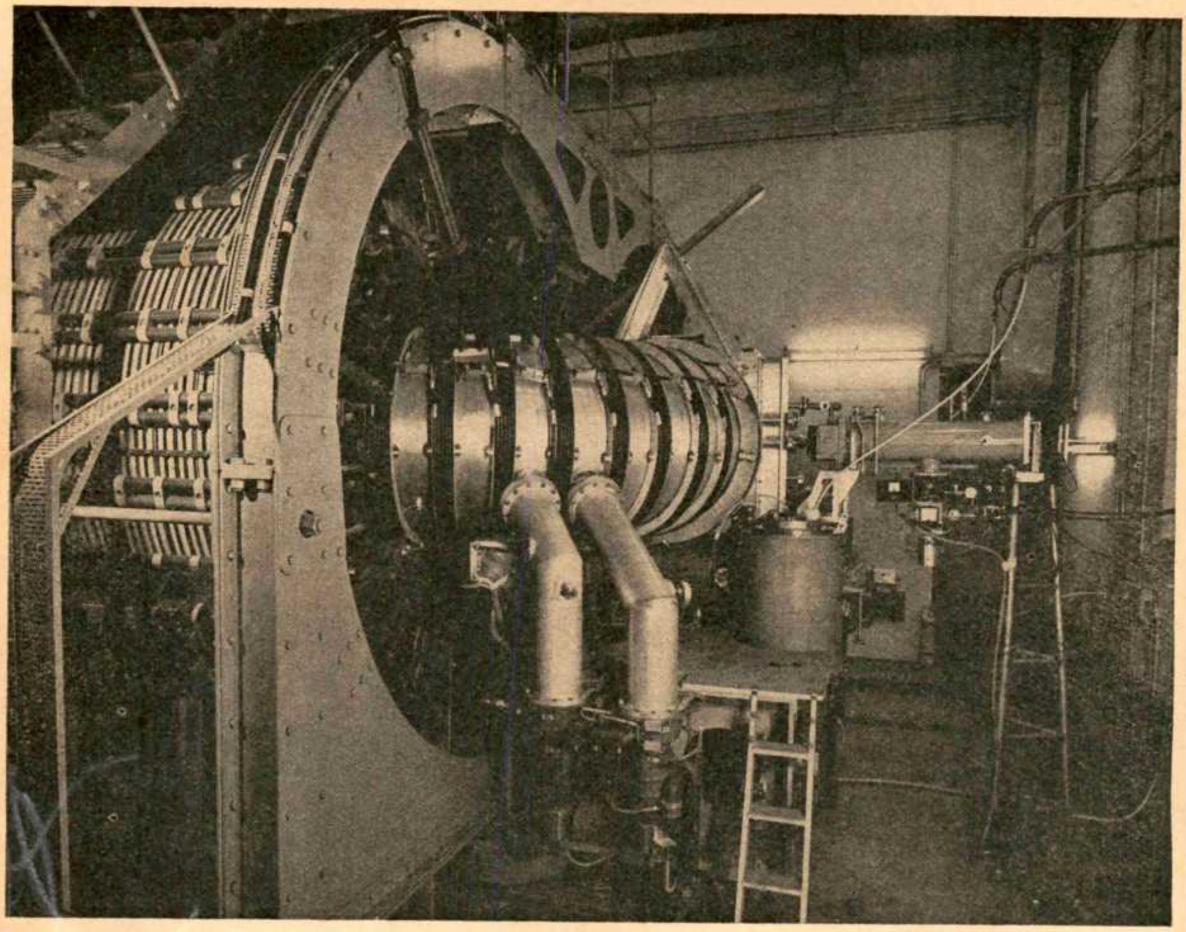

Fig. 1. Photograph of ZETA. The apparatus is enclosed in a room with concrete walls 3 ft. thick for radiation shielding

suppressed by the addition of 5 per cent nitrogen without affecting the neutron yield.

Stability

Measurements with magnetic field-probes and Langmuir probes, together with streak photographs of the current channel taken through a slit in the vacuum vessel, show the current channel to be quasi-stable and clear of the walls for the greater part of the current pulse. Fig. 3 is a reproduction of a streak picture of a helium discharge. The limit of the black area represents the internal diameter of the tube. The light recorded is that of the spark lines of impurities and of (He II) 4686 A. Streak pictures taken of discharges in deuterium are difficult to interpret as the light is emitted by neutral atoms and by impurity ions released into the current channel from the walls.

The centre of the current channel is displaced towards the outer wall due to the tendency of the ring current to expand. This expansion is opposed by eddy currents in the metal walls, which are of 1-in. thick aluminium. Measurements of the internal magnetic fields in the plasma are reproducible and show that the axial magnetic field, B_z, is trapped in the gas. On the axis it increases to approximately ten times the initial value. In general, the resultant lines of magnetic force due to the B_θ and B_z components are helical and vary in pitch over the cross-section of the plasma. The stability of a discharge with this magnetic-field configuration has not been treated theoretically.

The presence of the magnetic field-probe, which is 1 in. in diameter, greatly increases the discharge resistance and reduces the production of neutrons.

The diameter of the current channel estimated from the magnetic-field measurements and the streak photographs is between 20 and 40 cm. at peak current. Transmission measurements with 4-mm. microwaves demonstrate that the electron density

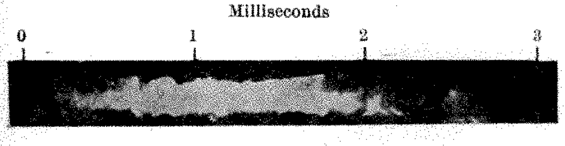

Fig. 3. Streak picture of a helium discharge. Conditions: initial gas pressure, $0{\cdot}25 \times 10^{-3}$ mm. mercury; axial field, 160 gauss; peak current, 130 k.amp. The tube walls lie at the boundary of the dark region

is greater than 6×10^{13} cm.$^{-3}$. This density is consistent with the assumption that all the gas present is ionized and contained in the current channel.

High-Energy Radiations

Neutron emission arising from the D–D reaction is observed for gas currents in deuterium in excess of 84 k.amp. Emission occurs for a period of about 1 msec., centred about the peak current.

Table 1 shows the average number of neutrons emitted per pulse as the peak current is increased.

Fig. 4 is a histogram showing the average rate of neutron emission during the current pulse.

The third column of Table 1 gives the temperatures required to produce the observed neutron yields assuming a thermonuclear process. In calculating these figures, it has been assumed that the current channel is 20 cm. in diameter, emits neutrons uniformly for a period of 1 msec. and all the deuterium initially present is contained in the current channel. Since the reaction-rate is an extremely sensitive function of temperature, variations in these parameters do not greatly affect the calculated temperature T_c. A comparison is made of the calculated and spectroscopically observed temperatures in Fig. 6.

Within the pressure-range investigated ($0{\cdot}8$–$10{\cdot}0 \times 10^{-4}$ mm.) the neutron yield decreased with increasing pressure. Neutrons were observed when 25 per cent of the gas initially present was nitrogen, but the yield was much reduced.

The results obtained with a directional neutron counter moved around the torus showed that, within a factor of two, the neutron emission was uniform and did not arise from localized sources.

No correlation is found between the time of neutron emission and the voltage fluctuations during the current pulse. However, neutrons are produced at the large voltage transient at the end of the pulse, but these can be eliminated by the addition of nitrogen gas.

X-rays are observed towards the beginning of the current pulse. Their average energy lies in the range 20–30 kV. and on the average some 10^6 quanta per pulse are emitted by the whole tube. The number and energy of the X-ray quanta are insensitive to gas pressure and current, but increase in intensity as the axial magnetic field is increased.

Spectroscopic Observations

Both arc and spark line intensities vary greatly over the period of the pulse. In general, emission lines of normal atoms and ions up to three times ionized have a maximum intensity before peak current. Fig. 5 shows the intensity variation of (He II) 4686 A. and (O V) 2781 A.

The Doppler broadening of spark lines emitted in a radial direction is used for estimating the kinetic ion temperature of deuterium and neon discharges. Small quantities of oxygen and nitrogen introduced into deuterium discharges provide spark lines in a convenient part of the spectrum. The breadth of the lines is of the order of 1 A. and can be measured with a quartz spectrograph having a dispersion of 20 A./mm. Calculations show that both Stark and Zeeman effects make a negligible contribution to the line-breadth. Mass motion may contribute to the observed broadening to an appreciable extent, but both probe and streak records show no evidence of

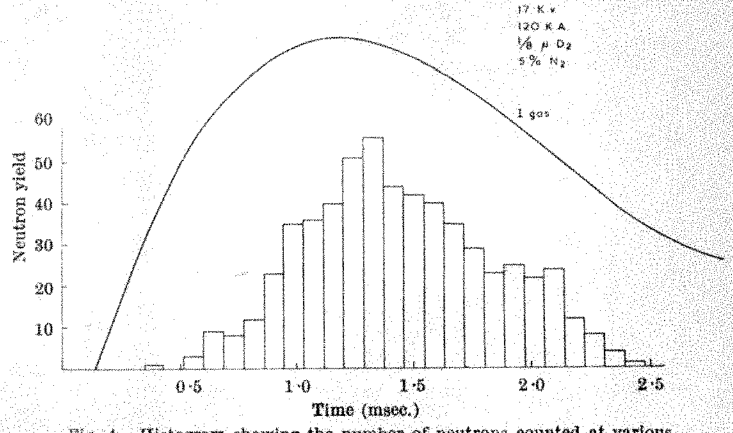

Fig. 4. Histogram showing the number of neutrons counted at various times during the current pulse

gross motion. The contribution to the line breadths of small-scale instabilities and turbulence remains to be measured.

Some 300 emission lines have been identified in the wave-length range 400–2500 A. The most prominent are those of oxygen, nitrogen, aluminium and carbon. Strong lines of (O VI) are recorded. In this wave-length range more than 400 lines remain unidentified.

The (O V) line has been used for Doppler breadth determination without time resolution as it has a maximum intensity in the neighbourhood of peak current. For (N IV) 3479 A. this is not so, and light was admitted to the spectrograph for a period of 1 msec. centred about peak current.

The kinetic temperatures obtained by observation of (O V) and (N IV) lines as a function of peak current are shown in Fig. 6. The ion temperatures are found to decrease with increasing initial pressure of deuterium. No satisfactory measurement of electron temperature has yet been made.

Conclusion

These preliminary results demonstrate that it is possible to produce a stable highly ionized plasma isolated from the walls of a toroidal tube. Hydrogen gas has been maintained in a state of virtually complete ionization with a particle density lying between 10^{13} and 10^{14} per cm.^{3}, for times of milliseconds. The mean energy of the ions in the plasma is certainly of the order of 300 eV., and there are many indications that the electron temperature is of the same order. The containment time and the high electrical conductivity are both adequate for the detailed study of magnetohydrodynamical processes.

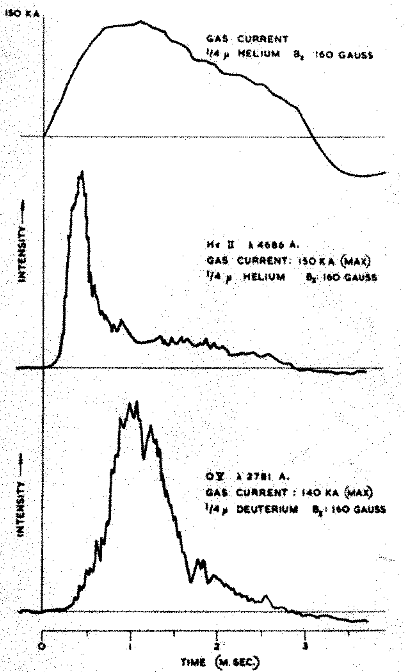

Fig. 5. The two lower traces are photomultiplier records of the intensity variation of two selected spark lines during the current pulse

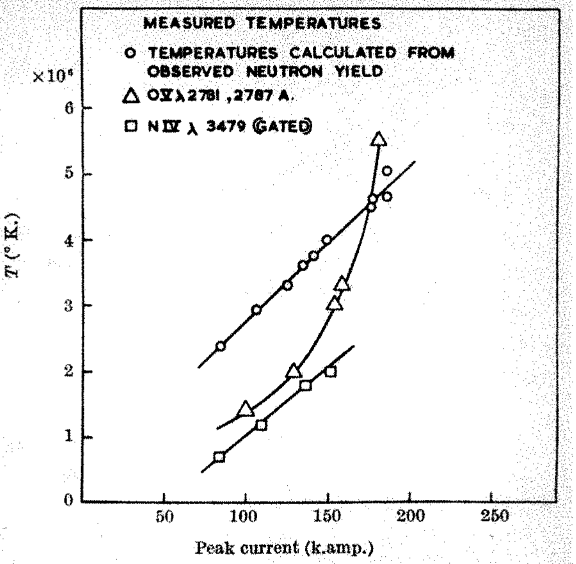

Fig. 6. Ion temperature as a function of peak current determined from the Doppler broadening of (O V) and (N IV). Conditions: initial gas pressure, 0·13 × 10^{-3} mm. deuterium and 5 per cent nitrogen; B_z = 160 gauss. The temperature of the deuterium gas, estimated from the observed neutron yield, is shown for comparison

To identify a thermonuclear process it is necessary to show that random collisions in the gas between deuterium ions are responsible for the nuclear reactions. In principle, this can be done by calculating the velocity distribution of the reacting deuterium ions from an exact determination of both the energy and direction of emission of the neutrons. The neutron flux so far obtained is insufficient to attain the desired accuracy of measurement.

Investigations leading up to the present results have been constantly encouraged and supported by Sir John Cockcroft and the late Lord Cherwell. The theoretical investigations have been directed by Dr. W. B. Thompson, of the Theoretical Physics Division.

A major part of the engineering design and construction of ZETA was done by the Metropolitan-Vickers Electrical Co., Ltd.

CO-OPERATIVE PHENOMENA IN HOT PLASMAS

By Prof. LYMAN SPITZER, Jun.
Princeton University

THE interesting results described by Thonemann and his co-workers in the preceding article provide not only an important step forward in the controlled release of thermonuclear energy, but also a challenging problem in the dynamics of fully ionized gases or plasmas. The spectroscopic line profiles and the neutron counts provide incontrovertible evidence for the acceleration of the positive ions. However, theory would seem to indicate that electron–ion collisions are inadequate to explain the observed rate of heating, and some unknown mechanism would appear to be involved.

The rate at which the positive-ion temperature increases, as a result of electron–ion collisions, has been given elsewhere[1]. It has been suggested, both in Great Britain and in the United States, that this process might be inadequate to explain the rate at which positive ions gain energy in certain electrical discharges. A relatively simple procedure, due to Stix[2], may be used to set an upper limit to the rate at which positive ions are heated by electron–ion collisions. In this method the rate of heating is made a maximum by setting the electron temperature equal to three times the ion temperature, T_i, and setting the electron density equal to a constant, n_e, corresponding to complete ionization and concentration within the discharge channel of all the gas initially present in the tube. On this basis (with $\ln\Lambda$ set equal to 15, see ref. 1) T_i is given by the relation

$$T_i^{3/2} = 1{\cdot}71 \times 10^{-2}\, n_e t \qquad (1)$$

where T_i is in degrees **K.**, n_e in electrons per cm.^{3}, and t in seconds.

To determine the density in the ZETA experiments, we compute the radius, r_d, of the discharge channel on the assumption that the flux of the axial magnetic field, B_z, is held constant in the gas during the contraction, and that the field, B_θ, due to the current equals the compressed axial field at the boundary of the discharge. As a result of the high temperatures achieved in ZETA, appreciable leakage of axial flux out of the discharge does not appear to be possible. Neglect of the finite gas pressure decreases the computed channel radius, increases n_e and again makes the rate of increase of T_i a maximum. On these assumptions, values of r_d have been computed for two currents, and an initial B_z of 160 gauss, and are listed in the second column of Table 1.

Table 1

I (amp.)	r_d(cm.)	n_e (cm.$^{-3}$)	T_i (°K.)	t(theor.)	t(obs.)
126,000	16	$8{\cdot}6 \times 10^{13}$	$3{\cdot}3 \times 10^{6}$	$4{\cdot}0 \times 10^{-3}$	$1{\cdot}0 \times 10^{-3}$
140,000	14	$1{\cdot}1 \times 10^{14}$	$2{\cdot}5 \times 10^{6}$	$2{\cdot}0 \times 10^{-3}$	$1{\cdot}0 \times 10^{-3}$

These values of r_d are consistent with those cited by the Harwell group. The values of n_e in the third column correspond to complete ionization of all the deuterium initially present in the torus, at a pressure of 1/8 μ, and its concentration in the current channel. The value of T_i for the lower current in column 4 is taken from Table 1 in the article by Thonemann *et al.*, and is based on the neutron yield. The value of T_i at the higher current is the temperature obtained from the Doppler width of the O V triplet, as shown in Fig. 6 of the Harwell article. The ion temperature obtained from the neutron yield under this condition is about 50 per cent greater, but no information is available on the time at which the neutrons appear in this case. In the fifth column are given the values of the time, in seconds, required for the positive ions to reach this temperature, computed from equation 1.

For comparison, the final column lists the observed times, in seconds, at which the positive-ion energies reach the values corresponding to the fourth column. For the lesser current, this is the time at which the neutron yield reaches half its peak value as shown in Fig. 4 of the paper from Harwell. For the greater value of current, t(obs.) is set equal to the time at which the O V radiation reaches its peak intensity, as shown in Fig. 5 of the Harwell paper. The simplifications made have tended to reduce t(theor.), and the correct value may be about an order of magnitude greater than given in Table 1. Thus the discrepancy seems real. There does not appear to be any simple model, based on a quiescent plasma, which is consistent with the observed rapid heating of the positive ions.

Following a suggestion by the Harwell group as to the importance of non-thermal heating processes, Stix[2] in 1956 arrived at conclusions similar to the above from experimental results obtained at Project Matterhorn. A discharge was produced in helium gas in a stainless-steel race-track tube of 10 cm. diameter and 240 cm. axial length, with an initial pressure of 0·63μ and an externally produced axial field of 19,000 gauss. The magnetic field was arranged so that intersection of the outer lines of force with material walls restricted the discharge to a channel of 5 cm. diameter. A loop voltage of 300 V. was applied around an iron transformer threading the race-track, and a maximum current of 8,000 amp. observed; since this current produces only a minor perturbation in the magnetic field, there was no pinching of the discharge. Time-resolved spectroscopic profiles of the He II line, λ 4686, indicated that the kinetic temperature of these ions increased to $1{\cdot}2 \times 10^6$ degrees K. in $1{\cdot}5 \times 10^{-4}$ sec., as compared to a theoretical maximum value of $0{\cdot}8 \times 10^6$ degrees in this same time-interval.

It has been known since the work by Langmuir[3] that electrons in a conventional gas discharge approach a Maxwellian distribution much more rapidly than can be explained by inter-particle collisions. Recent research by Gabor and his collaborators[4] has shown that oscillations generated in the plasma sheath are responsible for much of this effect, but the detailed mechanism is still unexplained. Possibly the high ion energies observed in ZETA represent a phenomenon related to Langmuir's paradox. To analyse the possible processes involved, such as oscillations, shocks, hydromagnetic turbulences, etc., it would be helpful to obtain information on the extent to which the positive-ion velocities are thermalized, that is, on how nearly the distribution function is isotropic and Maxwellian. Evidently detailed experimental investigations of these co-operative effects in hot plasmas will be of great interest in basic physics.

A STABILIZED HIGH-CURRENT TOROIDAL DISCHARGE PRODUCING HIGH TEMPERATURES

By Dr. N. L. ALLEN, Dr. T. E. ALLIBONE, F.R.S., D. R. CHICK, R. F. HEMMINGS, T. P. HUGHES, Dr. S. KAUFMAN, B. S. LILEY, J. G. MACK, Dr. H. T. MILES, Dr. R. M. PAYNE, J. E. READ, Dr. A. A. WARE, J. A. WESSON and R. V. WILLIAMS

Research Laboratory, Associated Electrical Industries, Ltd., Aldermaston Court, Aldermaston, Berks

SUCCESS in stabilizing a pinched toroidal discharge was first achieved in the apparatus known as ZETA at the Atomic Energy Research Establishment[1]. The stabilization was produced by applying a toroidal magnetic field (B_z) to a gas discharge combined with a metal-walled tube. A discharge similarly stabilized has been obtained in this Laboratory in a smaller apparatus, known as SCEPTRE III.

The discharge tube of SCEPTRE III was an aluminium torus having an internal diameter of 30 cm. and a mean torus diameter of 115 cm. A 4-ton iron core linked the torus with a primary winding of eight turns, wound close to the torus to keep the leakage inductance to a minimum. A condenser bank of 150 μF. charged to voltages up to 30 kV. was discharged through the primary by means of a spark-gap switch. A toroidal magnetic field of up to 1,000 gauss was produced within the torus.

Fig. 1 shows a plot of the peak gas current against applied magnetic field for discharges in deuterium at $3{\cdot}8 \times 10^{-4}$ mm. mercury pressure, the range of currents measured being from 20 to 200 k.amp. Typical

1·2	25	16	300	—	—	3·8	4·1
0·5	11	8	300	—	—	2·6	2·3

oscillograms of the voltage (V) measured around the torus, the gas current (I) and rate of change of current (dI/dt) are shown in Fig. 2. The marked change of (dI/dt) at t' occurs at that current for which the magnetic field at the wall (B_θ) due to the gas current is equal to the applied B_z field. Theory shows that when these fields are equal, the discharge leaves the walls and constricts, and a sudden change of effective inductance will occur because energy must be supplied to compress the gas and the B_z flux. The change of (dI/dt) at this point confirms this theory. A corresponding change occurs at the same current value when I is decreasing. This is consistent with an expanding discharge reaching the wall at this time. Measurements of inductance at peak gas current derived from the ratio $\left(\frac{dV}{dt}\Big/\frac{d^2I}{dt^2}\right)$ indicate that between 0·55 and 0·9 of the applied B_z flux is trapped by the constricting discharge.

Spectroscopic observations show the presence of a considerable amount of impurity in the discharge (oxygen, carbon, copper and aluminium). These impurities are thought to be produced by the arcing which occurs between the gaps which must be left in the metal walls of the torus. Ion temperatures have been measured by observing the Doppler broadening of the quadruply ionized oxygen lines by means of a Hilger medium quartz spectrograph. The line profiles obtained after allowing for instrumental broadening (by Voigt profiles) were found to be Gaussian down to 1/20 of their peak intensity: this is the experimental limit of observation. At 6×10^{-4} mm. mercury pressure, 15 kV. condenser voltage, and B_z 300 gauss, the line-breadth for the (O V) lines at 2781 A. was 0·97 ± 0·1 A., which with an instrumental width of 0·3 A. corresponds to a temperature of $2 \cdot 6 \times 10^6$ degree K. No temperature measurements have been derived when operating at less than 11 kV. condenser voltage because of the faintness of the impurity lines. Above this voltage the temperature has been found to decrease somewhat with increased voltage. This disappointing result must be due to radiation and other losses from the discharge increasing more than proportionately with voltage, caused by increased impurity; more arcing does occur at higher voltages.

To reduce the amount of impurity in the gas, experiments were carried out with a greater number of primary turns and hence a lower gradient for a given input energy. Since the impedance of the discharge channel is still predominantly inductive, the peak currents for a given input energy are only slightly reduced. Preliminary measurements with a 16-turn primary have yielded ion temperatures in the range $2 \cdot 5 \times 10^6$ to $3 \cdot 8 \times 10^6$ °K., the temperature increasing with condenser voltage up to 25 kV. With deuterium in the torus, neutron emission has been detected over the range of pressures 9×10^{-4} to 7×10^{-3} mm. mercury, a maximum occurring at about 2×10^{-3} mm. mercury, when the magnetic field is about 500 gauss. Table 1 gives some preliminary results for the total number of neutrons per pulse, and in some of the cases the corresponding measured ion temperatures. The temperatures in column 6 of Table 1 are calculated from the neutron yield, assuming a constant density within a discharge channel one-third the diameter of the tube and having a constant temperature for a period of 400 μsec.

Because of the impurities in the discharge, it emits sufficient light to be photographed. Fig. 3 shows a streak photograph of the discharge. The discharge is viewed at one point of the torus simultaneously through a slit window on top of the tube and on the side of the tube. Fig. 3a shows a print from a colour photograph which records both red and blue light,

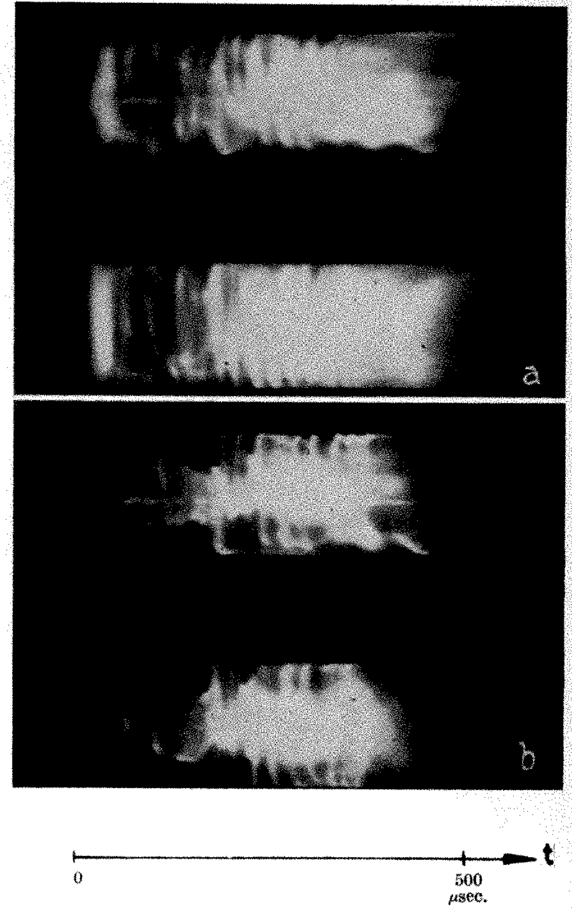

Fig. 3. Streak photograph of the discharge: (a) without filter; (b) with blue filter. Deuterium, $1 \cdot 2 \times 10^{-3}$ mm. mercury; current, 55 k.amp.; turns ratio, 8 : 1; magnetic field, 320 gauss

and Fig. 3*b* a print taken through a blue filter. The main discharge channel is blue and sharp-edged; its diameter decreases as the current increases and becomes unstable after about 300 μsec. when a/b reaches about 0·5, where a and b are the discharge and internal tube radii. The applied B_z was too small in this case to maintain stability throughout the whole pulse time. Superimposed on this channel are bars of light stretching across the whole tube which are mainly red at first, but later become white. These bars have been shown to travel around the torus with velocities of the order 2×10^6 cm. sec.$^{-1}$, and are believed to be due to shock waves produced by the intermittent arcing occurring at the gaps.

The observed results are consistent with the discharge being stabilized, due to the applied toroidal magnetic field being trapped by the constricting discharge. The theoretical conditions for such stability have been studied by Shrafranov[2], Tayler[3] and Rosenbluth[4]. Further properties of a discharge stabilized in this manner have been studied theoretically by Liley, of this Laboratory, in work not yet published. In particular, if the toroidal discharge is produced by discharging a condenser bank through a primary closely coupled with the gas current, the temperature reached at peak current is relatively independent of a/b within the range $1 > \frac{a}{b} > \frac{1}{3}$ and is given in degrees K. by:

$$T = 3 \times 10^7 \times J^{3/5}/(\gamma p b^4 E_0)^{2/5}$$

where J is the energy stored in the condensers in joules per cm. of the discharge tube-length, p the initial pressure of deuterium in microns, and E_0 the initial applied electric field in volts cm.$^{-1}$, γ is a factor near unity associated with skin effect, and b is in cm. This result has been obtained assuming that the gas kinetic pressure is small compared with the magnetic pressure, that the radial heat conductivity is sufficient to maintain uniform temperature across the discharge channel, and that the energy exchange time between positive ions and electrons is small compared with the period of the condenser discharge. Ohmic heating due to currents in both the z and θ directions is taken into account, as is also the effect of adiabatic compression as the discharge contracts. Radiation and other heat losses are neglected.

The temperatures calculated from the above formula are given in column 8 of Table 1; considering the simplifying assumptions which were made, these values agree reasonably well with the experimental observations.

We wish to thank Sir George Thomson for his advice and encouragement throughout this work, and to acknowledge the invaluable assistance received from colleagues at the Associated Electrical Industries, and in particular Mr. J. N. Barnett and Dr. S. E. Hunt; and the stimulus and help resulting from close collaboration with our fellow scientists at the Atomic Energy Research Establishment, Harwell.

MAGNETIC MEASUREMENT OF PLASMA CONFINEMENT IN A PARTIALLY STABILIZED LINEAR PINCH

By Drs. L. C. BURKHARDT, R. H. LOVBERG and J. A. PHILLIPS

Los Alamos Scientific Laboratory, University of California, Los Alamos, New Mexico

THE distribution of currents in a linear pinched discharge in deuterium has been measured by the use of small magnetic probes inserted into the plasma[1]. This report of work performed in mid-1956 describes the current distribution in a discharge which compresses a longitudinal magnetic field originally set up in the tube by an external coil. The stabilizing properties of an included longitudinal field have been discussed theoretically elsewhere.

The discharge tube was of the Columbus[2] design with an inside diameter of 6·8 cm. and an electrode spacing of 30 cm. Energy was stored in a capacitor bank of 75 μF. at 10 kV. The connecting circuit, consisting of ten ignitrons and coaxial cables in parallel, had an inductance of 0·12 μH., which allowed a peak current in the discharge of approximately $1{\cdot}5 \times 10^5$ amp.

The magnetic probes consisted of 44-turn coils of No. 40 wire on 1-mm. diameter forms. These were encapsulated in slotted hypodermic tubes which provided electrostatic shielding, and these in turn were surrounded by quartz jackets for insulation from the plasma. The coil output was integrated by

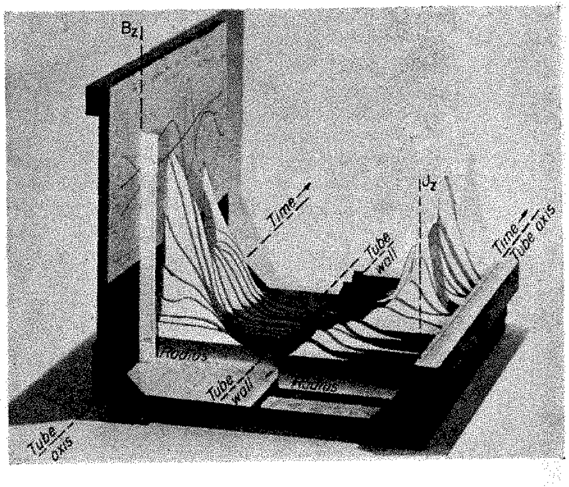

Fig. 1. B_z magnetic field and axial current density (J_z) distributions as a function of time. Initial conditions: B_z = 1,000 gauss; deuterium pressure, 600μ; V, 10 kV.

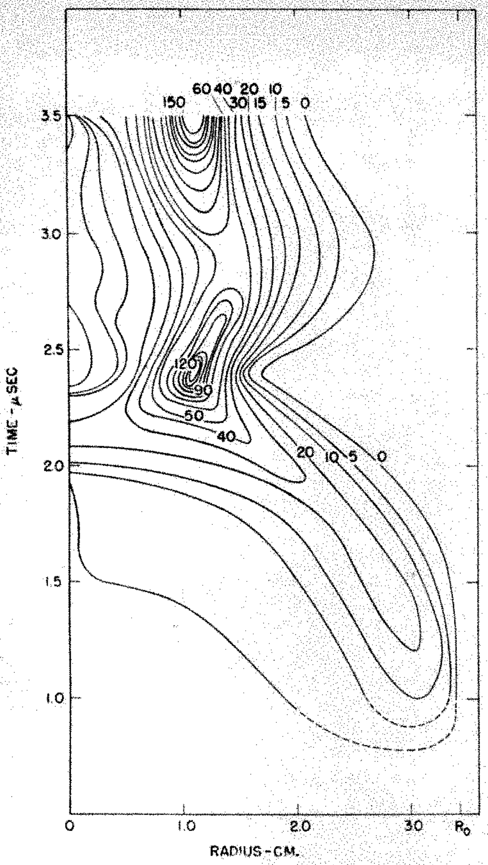

Fig. 2. Contour plot of axial J_z current density as a function of time. Same conditions as in Fig. 1

an RC network and displayed on an oscilloscope the sweep of which was triggered by the initial derivative of discharge current.

Plots of the B_θ and B_z fields were made by firing the tube and photographing the traces from the appropriately oriented probe at each of a family of equally spaced radial intervals. These traces of $B(t)$ for different radii were used for constructing curves of $B(r)$ for separate times. Differentiation of these traces then yielded distributions for j_θ and j_z. The requirement for good reproducibility of traces from shot to shot was well met up to approximately three microseconds, when the discharge, not completely stabilized by the 1,000-gauss B_z, went into a kink instability and became turbulent, filling the tube.

The experimental results for a discharge in deuterium at 600μ with 1,000-gauss B_z applied initially are shown in Figs. 1, 2 and 3. The discharge is seen to be compressed to approximately one third the tube radius and to oscillate about a mean value. The B_z field is compressed within the main current sheath.

If B_z and B_θ are known throughout the tube, and if one assumes the pinch to be in an equilibrium state, the plasma pressure may be calculated from the equation: $\mathbf{j} \times \mathbf{B} = \nabla p$.

In this case, the pinch was not entirely in equilibrium, as evidenced by a tendency to 'bounce' slightly at maximum compression. However, pressure balance calculations were made at times when the sheath acceleration was zero, where the above equation also applies.

Fig. 4 shows a plot of $B_z(r)$, $B_\theta(r)$ and $p(r)$ at 2·5 μsec. after firing the discharge. The pressure corresponds to a kinetic temperature of approximately 10 eV. if all the gas is assumed to have been swept in with the current sheath. In later stages in the discharge the maximum temperature before breakup was about 40 eV.

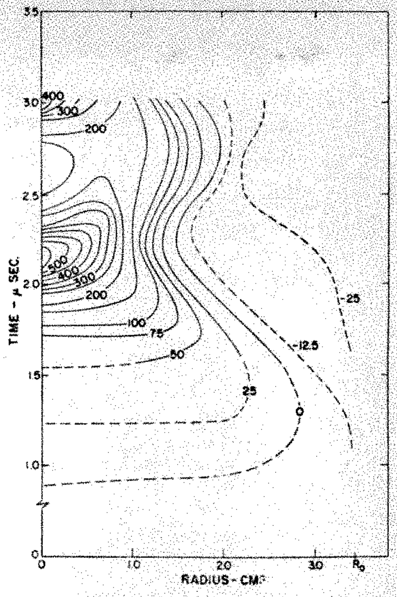

Fig. 3. Contour plot of B_z magnetic field as a function of time. Same conditions as in Fig. 1

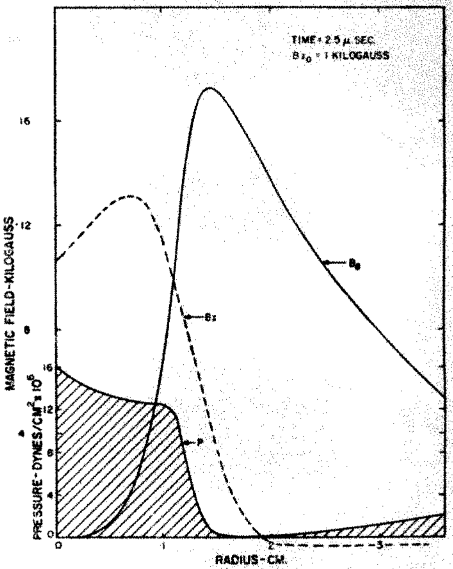

Fig. 4. B_θ and B_z magnetic fields plotted as a function of radius at 2·5 μsec. under conditions of Fig. 1. The radial material pressure as calculated from pressure balance considerations is also shown

We wish to acknowledge the encouragement of J. L. Tuck during this work. L. Fretwell assisted generously in the taking of results. We also acknowledge the pioneer (1954) work of J. W. Mather in the use of magnetic probes.

This work was performed under the auspices of the U.S. Atomic Energy Commission.

NEUTRON PRODUCTION IN A HIGH-POWER PINCH APPARATUS

By DRS. D. C. HAGERMAN and J. W. MATHER
Los Alamos Scientific Laboratory, University of California, Los Alamos, New Mexico

IN the work on fusion power devices, several investigators[1-5] have studied the neutrons produced by forming a pinch in deuterium. This communication reports on those neutrons coming from the Los Alamos Scientific Laboratory device known as Columbus II (July 1957). In view of the fast rate of growth of instability amplitudes in the pinch, Columbus II was designed as a high-powered machine in which the current reached its maximum value in as short a time as possible.

The Columbus II main condenser bank (shown in Fig. 1) consists of twenty-five 0·8 μF., 100-kV. low-inductance condensers on the periphery of a circle 14 ft. in diameter. The transmission line which connects the condensers to the centrally located discharge tube consists of two circular copper sheets separated by a ½ in. polyethylene insulator. This bank is switched by a graded vacuum spark gap (Hagerman, D., unpublished work), which is placed above the discharge tube. The condenser bank is charged by a Marx generator in 90 μsec. The inductance external to the discharge tube is 0·035 μH., which implies that under short-circuit conditions at 100 kV. the maximum current capability is 2·5 million amp. Typical operation is at 60 kV. with a gas current of 1 million amp. and a rise-time of 2 μsec. In addition to the main high-voltage bank, a second low-voltage bank (60 μF., 20 kV.) was available which could be used to form a partially stabilized pinch in the discharge tube before application of the high-voltage bank. The reason for this two-stage operation was the hope that the low-power pinch could be adiabatically compressed by the high-power bank beyond the region of stability to a high transient temperature. Axial magnetic fields up to 10 kilogauss were provided by an auxiliary low-voltage condenser bank. Ceramic discharge tubes (30 cm. long, 10 cm. in diameter) of sillimanite were found to allow operation up to 55–60 kV. An interesting difficulty has up to date prevented all effective use of the machine above 60 kV. The pinch phenomena can be identified by characteristic voltage or, in the case of extremely low inductance supply such as this one, current fluctuations observed during the discharge cycle. These are found to disappear at voltages above 55 kV. as do the neutrons.

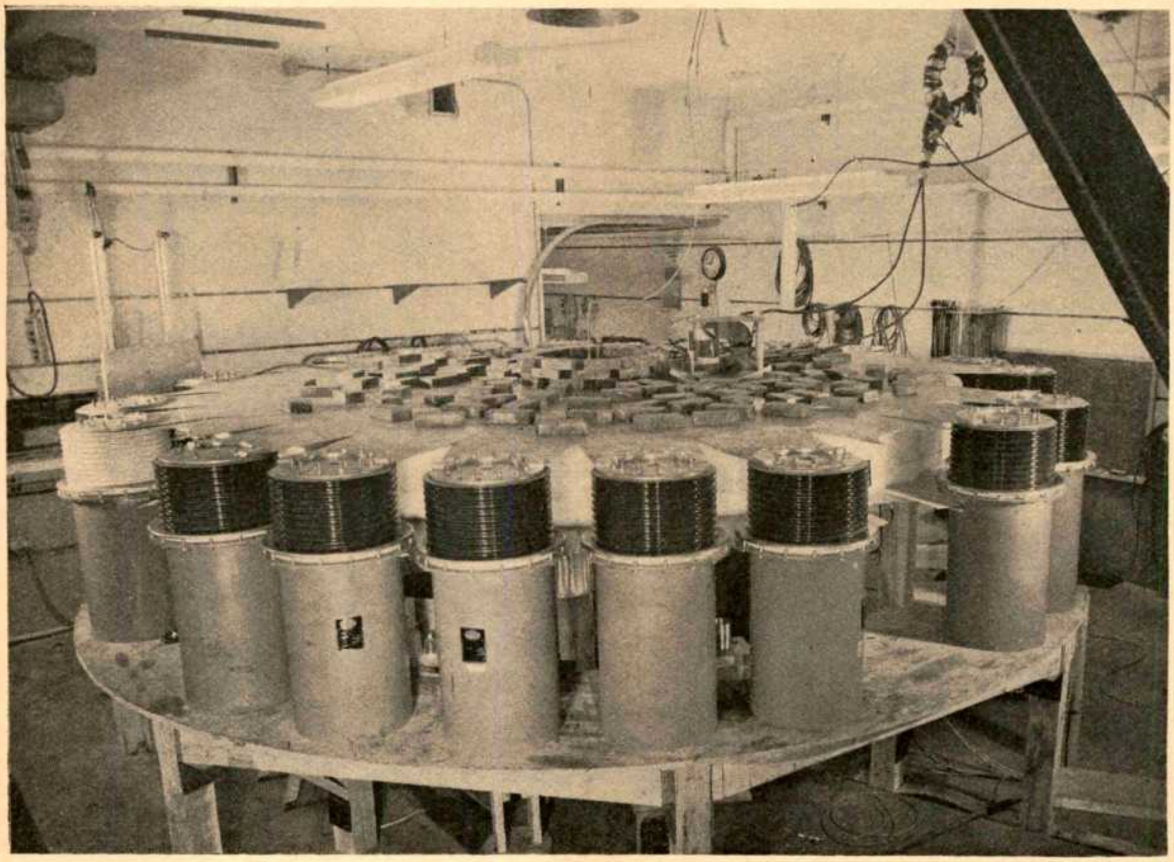

Fig. 1. General view of the apparatus

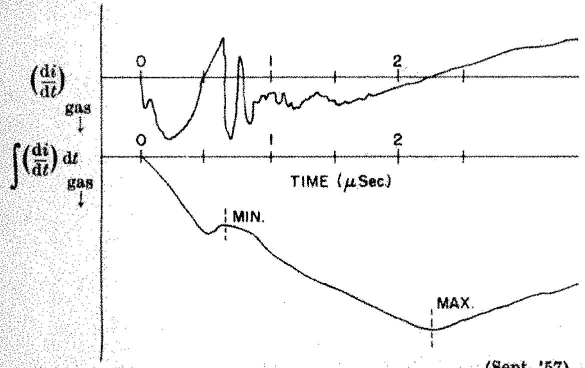
Table 1. COMPILATION OF TYPICAL DATA CHARACTERIZING NEUTRON OBSERVATIONS FROM LINEAR PINCHED DISCHARGES. (UNREPORTED DATA REPRESENTED BY BLANK SPACES)

	Electrical parameters			Neutron parameters								
								Neutron dependence on:				
Reference	V_0 (kV.)	$I_{max.}$ (k.amp.)	Rise-time (μsec.)	Pulse duration (μsec.)	Occurrence No. of bounces	Max. yield per pulse	Anisotropy in neutron energy (MeV.)	B_z field	Contamination	D_2 pressure	I or V	Neutron distribution
a 1	40	400	~8	~1·0	2	4×10^7			Strong. Vanish with 0·01 per cent H_2, A, Xe		Increase by 20 from 220 to 450 k.amp.	Uniform
b 2	35	~300	2·0	~0·3	2, 3, 4	10^7–10^8	~0·3	Strong. Decreased by factor 50 for 50 gauss	Strong. Decreased by factor of 50 for 8μ of A.	Peak at 200μ	Increase by 20 from 15 to 30 kV.	Uniform axial plates
c 3	15	250	5·0	0·1	2, 3	10^7–10^8	~0·26	Strong. Vanish with 100 gauss	Strong. Vanish with 0·2 per cent N_2. Decrease to ¼ for 5 per cent He	Peak at 125μ	Increase by 50 from 14 to 17 kV.	Linear increase from anode to cathode
d 4	10	300	5·0	~0·5	3	10^8		Weak. Decrease by factor 10 for 1,000 gauss	Vanish with 5 per cent N_2			
e 5 Columbus II	23	200	6½	~1·0	1, 2, 3							
f Preheaters alone	15	250	6	~0·1–0·3	1, 2	2×10^7		Strong. Decrease by factor 6 for 23 gauss				
g Main bank alone	50	800	2·0	~1·5	1	3×10^8	0·17	Weak. Decrease to ½ for 125 gauss	Weak. Decrease according to $(1-f)^2$ for He up to 50 per cent	Increase by 2·3 from 70 to 200μ of D_2	Increase by 2 from 40 to 50 kV.	Non-linear 0–5 cm. at anode. Uniform 5 cm. to cathode
h Preheater and main bank	50	~800	2·0	~1·0	1	7×10^7		Weak. Decrease to ⅓ for 90 gauss				

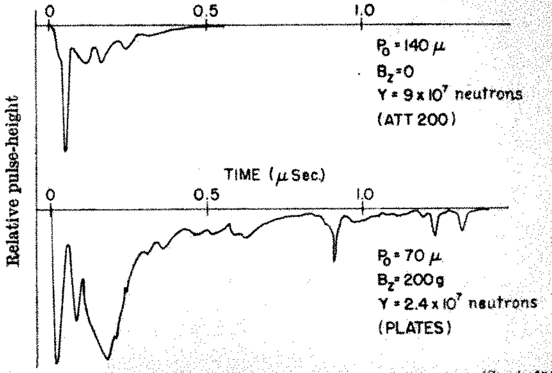
(*a*) *Low-voltage* (*preheater*) *bank alone.* Neutrons were produced in short bursts (0·1–0·3 μsec. long) occurring approximately at the time of the first and second contraction of the pinch. The maximum yield of neutrons was 2×10^7; the yield decreased by a factor of 6 by the addition of a 23-gauss axial magnetic field, which suggests that these neutrons may be produced by some instability mechanism. (One form of instability mechanism is discussed in ref. 3.)

(*b*) *High-voltage bank alone.* Fig. 2 shows d*i*/d*t* and *i* for 50-kV. operation. The neutrons appear shortly after the first contraction, as indicated by the small dip in the current. Fig. 3 shows typical neutron pulses with and without an axial (B_z) magnetic field. With no B_z field a short (0·3 μsec.) neutron burst with little or no tail was observed. A small B_z field lowers the relative height of the initial burst of neutrons and enhances the number of neutrons appearing in the tail of the neutron pulse. Neutron-pulse durations of up to 1·5 μsec. were observed with B_z fields as small as 200 gauss. The total yield of neutrons was rather insensitive to the axial magnetic field, dropping by only 55 per cent when the field was changed from 0 to 125 gauss. The maximum yield observed for zero B_z field was 3×10^8 neutrons. The dependence of the neutron yield on pressure and helium contamination showed: (1) that the yield was proportional to the pressure, increasing by a factor of 2·3 between 70 and 200μ; (2) the fraction f of the helium contamination lowered the yield according to the expression $(1-f)^2$ (these results were obtained with a B_z field of 200 gauss). Fig. 4 shows the axial neutron energy distribution from nuclear



(Sept. '57)

Fig. 2. Gas current and $(di/dt)_{gas}$ vs. time



(Sept. '57)

Fig. 3. Typical neutron pulse shapes

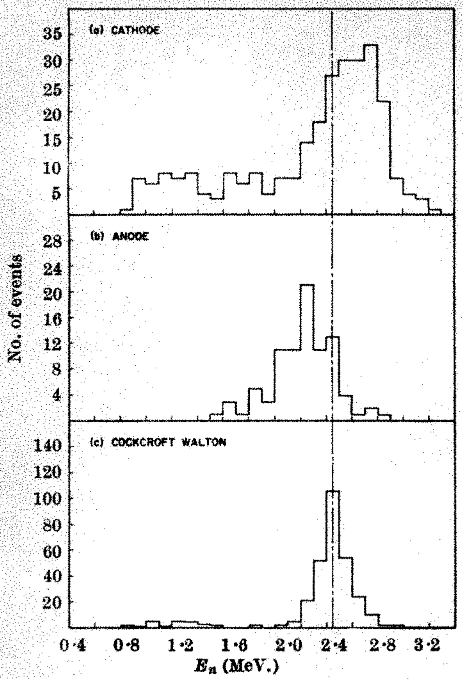


Fig. 4. (*a*) and (*b*) show the axial neutron energy distribution; (*c*) a range-energy calibration using a Cockcroft–Walton machine

plates situated behind the cathode and anode. The observed energy shift of approximately 0·17 MeV. corresponds to a 20-keV. deuteron colliding with a deuteron at rest, or to a group of interacting deuterons travelling toward the cathode with a velocity of 7×10^7 cm./sec. Plates were also exposed radially at three positions along the discharge; the results are compatible with a uniform neutron distribution from the cathode to within 5 cm. of the anode, beyond which the yield is lower. All the plate exposures were made with a 200-gauss B_z field and 50-kV. bank voltage.

(*c*) *Operation of banks in combination.* These results are preliminary. (1) Time-sequence operation was achieved; however, timing had little effect on neutron yield if the fast bank was timed prior to the development of instabilities in the first-stage pinch. (2) Neutron pulse widths were approximately 1 μsec. (3) Neutron yields were approximately 10^7/pulse. (4) A 90-gauss axial magnetic field reduced the yield by a factor of 3. (5) Neutron yield increased by a factor of 2 in going from 40 to 50 kV. on the high-voltage bank. In Table 1 the above results are compared with those reported by other laboratories.

The dependence of neutron yield (row *g*, Table 1) on applied magnetic field, helium contamination, gas pressure and voltage, as well as the long neutron pulse-duration, suggests a mechanism of neutron production different from the usual instability process. However, it is clear from the anisotropy in the neutron energy spectrum at 200-gauss axial magnetic field that directed motion of the reacting deuteron system exists. This anisotropy is smaller than that reported (row *b*, *c*, Table 1) for instability neutrons without axial magnetic field, even though the applied electric field in Columbus II is appreciably larger.

We are indebted to J. L. Tuck and J. A. Phillips for many helpful discussions concerning this experiment. Thanks are also due to L. Rosen and the nuclear plate group for their generous assistance, to J. H. Coon for the provision of D–D calibration neutrons, to L. Neher for assistance in fast-scintillation techniques, and to A. H. Williams and Glen Livermore for their technical assistance throughout.

NEW CONFINEMENT PHENOMENA AND NEUTRON PRODUCTION IN A LINEAR STABILIZED PINCH

By Drs. L. C. BURKHARDT and R. H. LOVBERG

Los Alamos Scientific Laboratory, University of California, Los Alamos, New Mexico

A LINEAR discharge device[1], designated Columbus *S*–4, has been constructed to test the effect of increased tube diameter and inter-electrode spacing on the properties of a B_z-stabilized pinched discharge. The apparatus utilizes the same capacitor bank as that employed in the magnetic-probe experiments (75 μF., 20 kV.) with the external inductance reduced to 0·075 μH. The discharge tube is a cylinder of porcelain ('Mullite') of inside diameter 5·0 in. and 24 in. spacing between electrodes. A close-fitting cylindrical return conductor of 1/16 in. stainless steel provides negligible delay in the 2-msec. rise of the longitudinal (B_z) field which is set up by an external solenoid and capacitor bank. Provision has been made for radial insertion of a magnetic probe halfway between the electrodes.

From the time of its initial operation, this tube has exhibited properties qualitatively different from those observed in previous experiments. Initial observations of optical spectra from the discharge were made with a monochromator of approximately 1 A. resolution which looked along the tube axis. After the tube had been operated for about one hundred discharges, it became impossible to detect the spectra of the common impurities such as silicon and oxygen until the peak of the second half-cycle of discharge current. The photomultiplier gain was set an order of magnitude higher than the value adequate for use

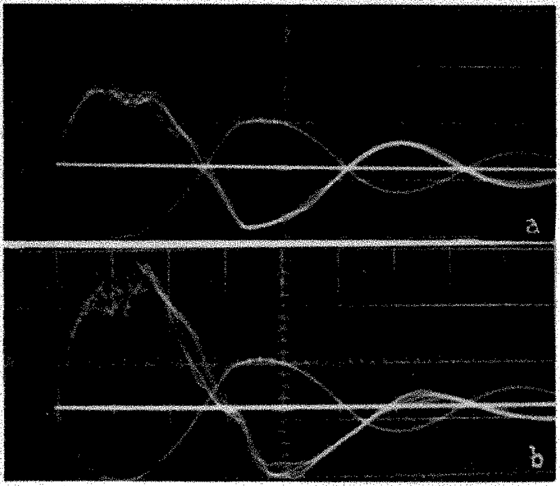

Fig. 1 (a) Four superimposed traces of $B_\theta(t)$ for a radius of 6·4 cm. (tube-wall radius). The capacitor bank current is shown in opposite polarity. Sweep: 5 μsec./cm. (b) B_θ traces for $r = 4 \cdot 4$ cm.

on previous systems. The H_β line, under these conditions, appeared with considerable amplitude during the initial discharge current rise, dropped to an almost undetectable amplitude near the first current maximum, and remained faint until the second current maximum, when it again became prominent. The rise in gas pressure after each shot was less than 5 per cent. Operating conditions for the above observations were:

Condenser voltage = $1 \cdot 5 \times 10^4$ V.
B_z = 1,750 gauss
Deuterium pressure = 40μ mercury
$I_{\text{max.}}$ = $2 \cdot 5 \times 10^5$ amp.
Time to first current peak = 6 μsec.

Magnetic-probe measurements of the B_θ and B_z fields were made under these conditions, and for times extending through three half-cycles of the bank current. While the shot-to-shot reproducibility of the probe traces became imperfect after 3 μsec., due to an apparent small-amplitude flutter of the plasma column, the spread in the trace amplitudes was still sufficiently small to allow the plotting of meaningful field distributions and the calculation of approximate plasma pressures. Figs. 1a and 1b are B_θ records for radii of 6·4 cm. (the tube wall) and 4·4 cm. respectively. Four traces are superimposed in each picture, and the capacitor bank current is also displayed in opposite polarity. The sweep-speed is 5 μsec. per cm. An unexpected effect is seen to manifest itself after a time of 3 μsec. While before this time the amplitudes display the $1/r$ dependence characteristic of all current being within 4·4 cm. radius, this dependence breaks down at later times in the half cycle; in particular, the amplitude ratio between the two sets of traces at 10 μsec. exceeds a factor of two. This implies the existence of a sheath of negative current just inside the tube wall. The same conclusion can be drawn by comparing the B_θ amplitudes at the zero of input current; no net current flows inside the tube, since B_θ at 6·4 cm. is zero; yet about 5×10^4 amp. is flowing inside 4·4 cm. radius. A circulation of current is evidently taking place inside the tube. Later in the cycle it is seen that when the central core current has dropped to zero, the entire bank current is flowing in the outer sheath; this proceeds to pinch, and the above process is repeated. It is noteworthy that contaminant spectra appear only at the compression of this second sheath; wall materials have apparently collected in it during its relatively long existence at the wall.

A pressure-balance calculation has been done using the B_z and B_θ amplitudes at 6 μsec. after the starting of current, that is, at the current maximum. The plasma pressure at the tube axis and at this time appears to be about 12 atmospheres; if the plasma is assumed to be uncontaminated and pinched to the same radius as the longitudinal current, the temperature should be in excess of 300 eV.

Since a temperature as high as this, together with the assumed central density, should result in an easily detectable neutron yield, namely, of the order of 100/c.c.-μsec., a series of counter experiments was performed. A plastic scintillation counter was found to give pulses centred at the current maximum, and tests with paraffin interposed between the counter and discharge tube established the radiation to be neutrons. The yield was found to be too small to activate a silver foil counter to significantly greater than a background count, and it was concluded from the known counter calibration that the total yield was fewer than 10^5 per discharge. The numbers of counts observed in the plastic scintillators made it apparent that some of the discharges yielded more than 10^3 neutrons. At the time of writing, the number has not been accurately fixed. Fig. 2 shows the output of the scintillation counter for several successive discharges, along with a trace of the condenser current. In this instance, the condenser voltage had been raised to 17·5 kV.

Runs were made to measure relative neutron yield as a function of bank voltage, B_z, deuterium pressure, and contaminant fraction in the gas. The yield over the half-cycle was obtained by integrating the photomultiplier anode current for this time. Ten shots were taken at each condition of the system. In Figs. 3, 4, 5 and 6 the relative yield for each discharge is plotted as a small dot, while the mean values are horizontal bars.

It must be remarked that most of the data plotted in the above figures were taken at conditions more favourable for neutron production than those used for the magnetic-field measurements. However, counts were observed in significant numbers at 15-kV. bank voltage and 1,750-gauss B_z; typically, one observed the order of 10 counts per discharge in a 5 in. × 5 in. cylindrical plastic scintillator placed

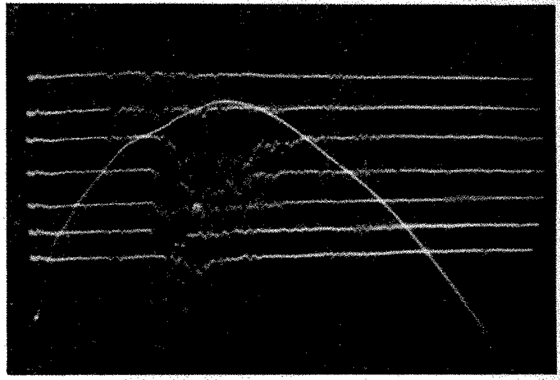

Fig. 2. Traces of plastic scintillator output vs. time; sweep, 2 μsec./cm. Capacitor bank current is superimposed

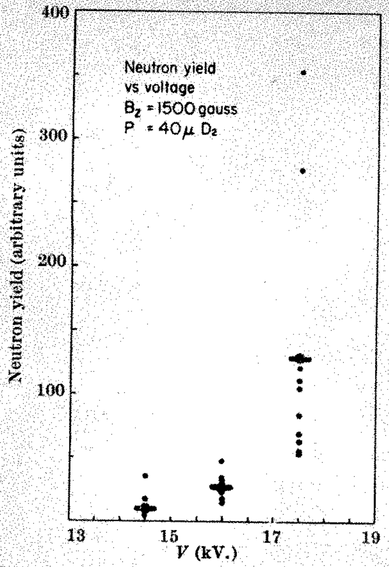

Fig. 3. Neutron yield vs. capacitor bank voltage. The small dots represent yields for individual discharges; ten discharges were measured at each value of *V*. The bars are mean values for the ten points

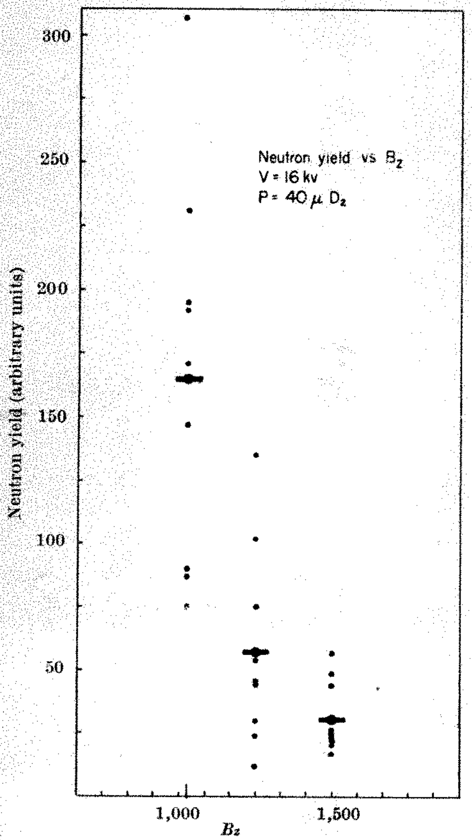

Fig. 4. Neutrons vs. B_z

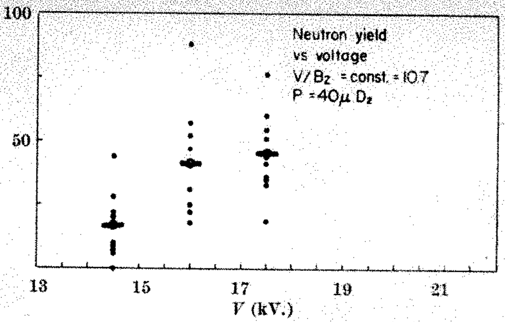

Fig. 5. Neutrons vs. *V* for V/B_z held constant at 10·7

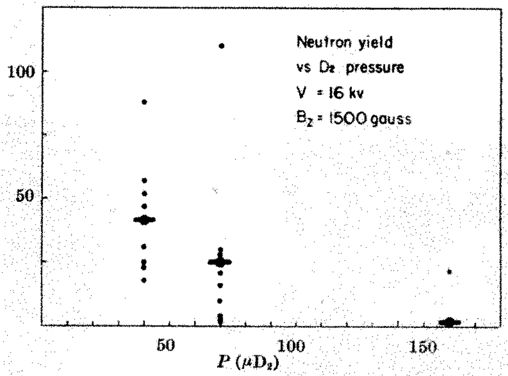

Fig. 6. Neutrons vs. deuterium pressure

8 in. from the centre of the tube. At this condition, as in Fig. 2, the neutrons are produced in a time interval 4 μsec. wide, centred near the current maximum.

While the pinch configuration for the case of the measured field distribution (15-kV. bank voltage, 1,750 gauss B_z) is clearly stable against break up by kinking, and the 16 kV., 1,500-gauss condition also appeared stable in this sense from initial probe surveys, it is not established that the runs which involve higher ratios of bank voltage to B_z are stable. One must, therefore, allow the possibility that the neutron output in the lowest B_z and highest bank voltage cases results from some acceleration mechanism associated with instability. Even in the configuration of which B_θ traces are shown, the fluttering of the fields near maximum current may represent strong local field inhomogeneities which could provide a particle-accelerating mechanism. It is clear, however, that the variations of yield with *V* and B_z are consistent with a thermonuclear origin of the neutrons, since the plasma compression and current density are sensitive to variation of these parameters.

The lower limit of gas pressure was set by the inability of the tube to break down at less than 40μ.

A contaminant of 5 per cent air in the deuterium reduced the neutron output to less than a tenth of its normal value.

Work is progressing on the problem of determining pinch stability for the conditions where it is now uncertain. An effort will also be made to measure the degree of energy isotropy of the neutrons, since anisotropic energy distribution has in the past identified the neutron yield from several devices as being non-thermonuclear[2].

We wish to thank J. L. Tuck and J. A. Phillips for helpful discussions during the course of this work. We also acknowledge the contribution of H. Dreicer in predicting theoretically the entrapment of wall impurities by a plasma sheath.

This work was performed under the auspices of the U.S. Atomic Energy Commission.

NEUTRONS FROM A STABILIZED TOROIDAL PINCH

By Drs. J. HONSAKER, H. KARR, J. OSHER, J. A. PHILLIPS
and J. L. TUCK

Los Alamos Scientific Laboratory, University of California, Los Alamos, New Mexico

HYDROMAGNETIC calculations on idealized models of the pinch have indicated that stability might be attained by a combination of a central axial magnetic field and conducting walls, provided that certain restrictions on compression and $8\pi p/B^2$ (p is plasma pressure) are obeyed[1-5]. The problem is actually more complicated than these simple models suggest, especially when the finite thickness of the boundary layer between external magnetic confining field B_θ and internal magnetic stabilizing field B_z is taken into account.

Experiments at Los Alamos on straight tubes[6] using magnetic probes have measured substantial plasma pressure confinement with appreciable stability by these means. It proved unexpectedly difficult to do as well in toroidal geometry, due in part to the technical difficulty of inducing high-voltage gradients and also to the presence of unavoidable gradients in electric and magnetic fields across the discharge tube cross-section. After a progression of machines extending over several years, Perhapsatron S–3 began to show (middle 1957), by magnetic probe measurements[7], more symmetrical detachment of the current channel from the walls. This apparatus is shown in Fig. 1.

Fig. 2 shows a magnetic pressure measurement with plasma pressure (nkT) determination made in Perhapsatron S–3 at two stages in the current wave $t = 4$ μsec., $2\cdot0 \times 10^5$ amp., and $t = 6$ μsec., $2\cdot3 \times 10^5$ amp. Such curves show penetration of the B_θ magnetic field towards the pinch axis with some increased confining current density along the axis and little current outside the pinch. We evaluate nkT by substitution in the pressure balance equation :

$$\left[nkT + \frac{B^2}{8\pi}\right]_{r_1}^{r_2} = -\frac{1}{4\pi}\int_{r_1}^{r_2}\left(\frac{B_\theta^2}{r} + \frac{B_z^2}{r}\right)dr + C$$

where $B^2 = B_\theta^2$, r and R are the radii of curvature of B_θ and B_z respectively, and C is a constant evaluated at some position at which nkT is known. The calculations of nkT are not precise, since (1) the radii of curvature of the magnetic field lines are assumed from symmetry and (2) uncertainties of the position of the discharge axis seriously affect the integration in its vicinity. The pressures are consistent with appreciable average temperatures greater than 125 eV. Also the cooling effect of impurity influx from the walls is suggested by the lower pressures at 6 μsec., compared with those indicated at 4 μsec. This is paralleled by the rise in impurity spectral line inten-

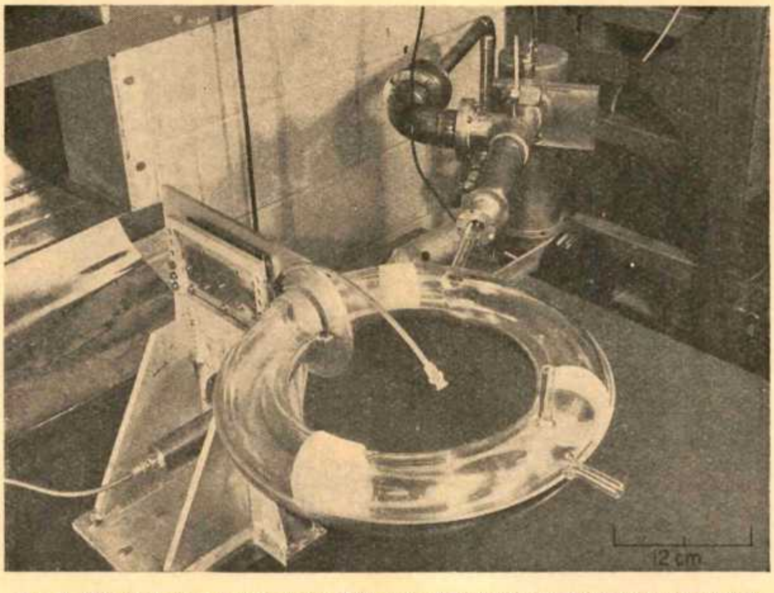

Fig. 1. The glass torus (minor radius 2·65 cm.) of Perhapsatron S-3 is shown supported in the lower half of the copper primary (major radius 16·2 cm.). The condenser is 225 μF. (44,500 joules at 20 kV.) with a total connected inductance of 0·08 μH. at the torus feed-point

sities emitted from the discharge, up to this time quite faint (Fig. 3*f*). It was also observed that the small magnetic probe, diameter 1·7 mm., when extended into the discharge, caused the impurity lines to appear earlier. This suggests that the temperature would be higher and the current sheath thinner when the probe was absent.

A large liquid scintillator (43 cm. diameter, 50 cm. high) showed neutron emission (December 17, 1957) of 10^4 per discharge. Substitution of a quartz ('Vycor') torus for the 'Pyrex' glass one raised the average output to 2×10^5 neutrons per discharge. Addition of a laminated iron core improved the coupling in the early stages of the current cycle before it saturated, and gave a further small increase. Neutron yields up to 10^6 per discharge have been observed.

Neutron intensity versus time as detected by a proton recoil scintillation counter shows a burst of duration approximately 2 µsec. starting at about 3·0 µsec. after gas breakdown, with successive smaller bursts superimposed on a tail of duration 10–15 µsec. (Fig. 3*c*). It seems definite that some neutron emission continues through the discharge current zero and occasionally up to and beyond the second current maximum (~30 µsec.). A pulse of neutrons is at times associated with the second current zero ~60 µsec. This may have interesting implications. There is a well-defined optimum B_z, with no yield at zero B_z (Fig. 4). The yield rises with diminishing deuterium pressure, and the lower limit in this direction is determined by failure to obtain gas breakdown (Fig. 4) even with radio-frequency pre-excitation. The yield is sensitive to contaminants and to the quality of the base vacuum pressure. 5 per cent nitrogen reduces the yield by a factor of 2 (Fig. 5). Yields are variable at fixed operating conditions by a factor of about 3.

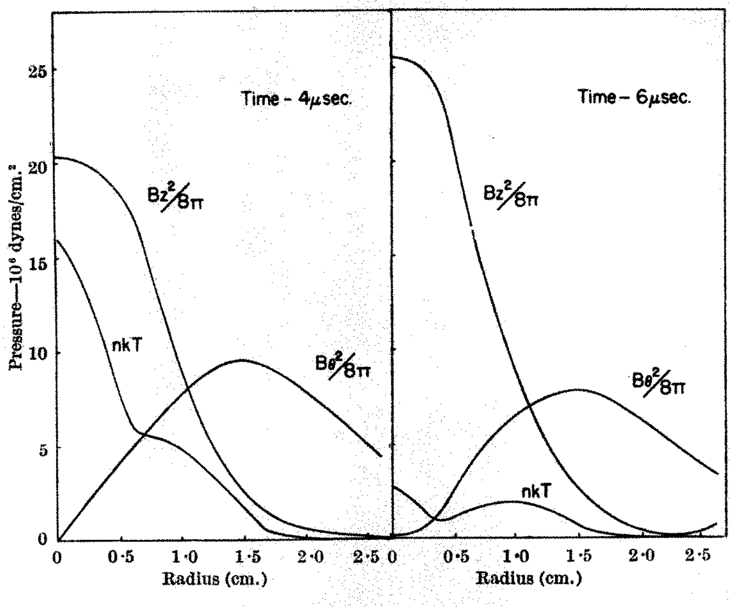

Fig. 2. Magnetic field pressure distributions as a function of radius at $t = 4$ µsec. and 6 µsec. The material pressure (*nkT*) distributions calculated from pressure balance considerations are also shown

X-rays appear in a sharp burst, duration approximately 1 µsec., about 0·9 µsec. after gas breakdown, which is before the time of neutron emission. Little or no X-ray yield is observed under the conditions of maximum neutron yield. The X-ray intensity increases with deuterium pressure, whereas the neutron intensity increases with decreasing pressure. At high pressures (400µ), X-ray energies as high as 0·9 MeV. have been measured with 12 kV. primary voltage and 5,000 gauss B_{z_0}.

A spectrogram taken during three complete discharges at 11 A. per mm. dispersion over range 3000–6600 A. shows a strong continuum throughout, with a few lines greatly broadened ~30 A. tentatively identified as Si II, Si III.

One of the central features of the design of Perhapsatron *S*–3 is the thinness (0·3 cm.) of the glass walls of the torus and its close fit to the metal primary, based on the unequivocal predictions by theory of the bad effect of B_z external to the pinch on stability. This has made the glass torus very fragile and easily broken by strains transmitted to it from the heavy primary under electromagnetic forces. The neutron yield rises between 14 and 15 kV. primary voltage, with higher voltages limited by failure of the glass torus. A precision alumina porcelain torus when delivered is expected to reduce these difficulties, with the possible added advantage that alumina is known from other experiments to be superior to quartz in the contaminants it supplies to the discharge.

A temperature of 600 eV. (compression 9) would be consistent with the observed yield of neutrons, and the pressure balance equations would support this. Magnetic probes indicate that the pinch undulates as a whole with an amplitude of about 2 mm. The diminution in neutron yield after the initial burst is a matter for concern and finds an explanation in terms of cooling by the influx of impurities (~3·6 µsec.). The observed sensitivity to impurities is supporting evidence for a thermonuclear reaction but has been misleading in the past—

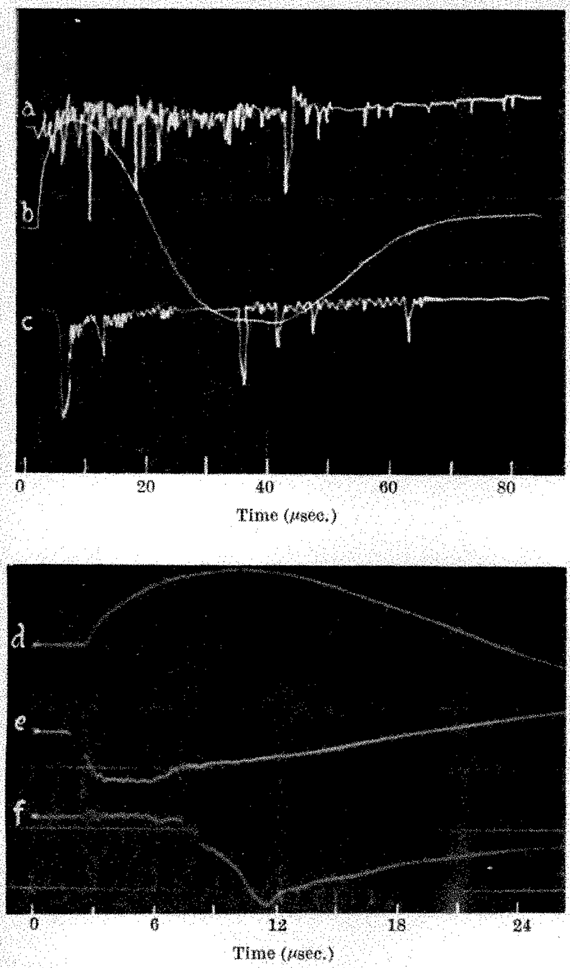

Fig. 3. Multiple-beam oscilloscope traces as a function of time of: *a*, neutron capture γ-rays from a cadmium-loaded liquid scintillator; capture half-life ~ 30 μsec.; *b* and *d*, gas current; *c*, proton recoils from a fast scintillator; *e*, secondary voltage; *f*, intensity of silicon line, 4128 A.

witness the great sensitivity of instability neutrons to impurities[8–10].

We think it fairly safe to say that at any rate the fringe of thermonuclear temperatures of approximately 500 eV. is being approached. The principal anxiety arises from the fact that it is precisely at this point that conditions are ideal for simulation of a thermonuclear reaction by a Fermi mechanism[11]. Reflexion of deuterons from magnetic disturbances travelling at the Alfvén speed $\sqrt{B^2/4\pi p}$, give deuterons in the 12-keV. energy-range after very few reflexions, yet a small fraction of the gas, 0·6 per cent with this energy, equals the thermonuclear yield of a plasma at 600 eV. Nor is it easy to distinguish the two experimentally. Refined nuclear emulsion techniques could do it, but would require several thousand discharges to accumulate enough intensity at the present output-level of Perhapsatron *S*–3. Comparison of yields with DD and DT gas fillings can also be used, but requires more reproducibility than prevails at present.

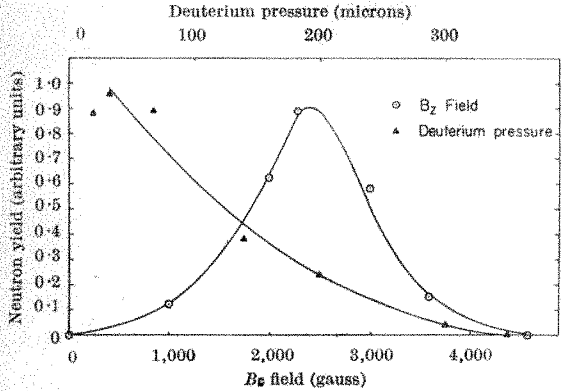

Fig. 4. Neutron yield versus initial longitudinal B_z magnetic field and deuterium gas pressure. The experimental points are averages of several runs with variations of a factor 3 in neutron yield

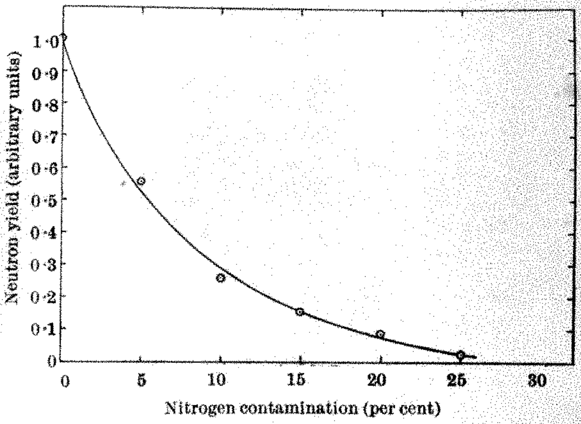

Fig. 5. Neutron yield versus percentage nitrogen contaminant (mean of several runs)

We acknowledge with pleasure the co-operation of L. Burkhardt and R. Lovberg for scientific contributions to the experiment, of R. Dike for engineering design, of A. Schofield for electrical design, of A. Roensch for inspired precision glass-blowing with difficult materials, and of J. M. B. Kellogg for co-operation in the division.

We are indebted to the Atomic Energy Research Establishment, Harwell, for assistance in handling this paper for publication simultaneously with the ZETA experiments (which, incidentally, preceded this work by several months).

This work was performed under the auspices of U.S. Atomic Energy Commission.

OBITUARIES

Prof. M. A. Catalán

Miguel Antonio Catalán was born at Saragossa in Spain on October 9, 1894, and died at Madrid on November 11, after a brief and unexpected illness, at the age of sixty-three.

Following graduation at the University of Saragossa, Catalán received his Ph.D. degree with honours at Madrid in 1917 and started research work on spectroscopy in the laboratory for advanced studies of the Department of Physics. With a Spanish fellowship, he studied in England under Prof. Alfred Fowler's direction in 1920–21. During this stay at the Imperial College of Science and Technology, Catalán made his most important contribution to spectroscopy with the discovery of multiplets in the arc spectrum of manganese. For the first time, the spectrum of a complex atom could be interpreted, giving experimental support to the quantum theory of those atoms. Catalán's discovery was the beginning of a novel approach to the study of atomic spectra, and all laboratory spectroscopists began to study many other complex spectra, looking for multiplets as Catalán did in Mn I.

In 1923 he was awarded a Rockefeller Fellowship, at the suggestion of Prof. A. Sommerfeld, and worked with him during 1923–24. Back in Spain, Catalán continued his work on atomic spectra, and in 1930 was promoted head of the Atomic Spectroscopy Section at the Rockefeller Institute of Madrid. Many students from Spain and abroad worked under his direction, and in 1934 he became full professor in the University of Madrid. During the following years, a large number of important papers on analyses of atomic spectra were published by Catalán and his students; thus, very soon his school was well known and appreciated all over the world. Invited by the American Philosophical Society, he worked in the United States during 1947–48 and again in 1950 and 1951. In 1950 he was appointed chief of the Department of Spectroscopy in the newly created Institute of Optics, Madrid; and in 1952 he was elected to the Joint Commission for Spectroscopy of the International Council of Scientific Unions. His important contributions to the field of atomic spectroscopy were also rewarded in Spain when he was elected member of the Real Academia de Ciencias in 1955. At the invitation of South American universities, Catalán lectured in Argentina and Venezuela in 1956 and 1957. Up to the date of his illness, he was still very active and productive; thus his death surprised and shocked all his friends.

Prof. Catalán was not only an eminent spectroscopist; he was also a great teacher and he enjoyed lecturing to students or to any type of audience. Teaching was really his hobby. He had the rare ability of making simple and understandable the most difficult subjects, and he liked these outside activities so much that, apart from his lectures at the University, he always instructed groups of high-school students.

Catalán was friendly and helpful to everyone. He was liked and admired by all who knew him, and he will be remembered with affection by his many friends and colleagues. R. Velasco

Prof. Louis Pillemer

Louis Pillemer, well known to many immunologists in Great Britain, died unexpectedly on August 31, 1957, at the age of forty-nine years.

Born in South Africa, Pillemer spent all but the first year of his life in the United States. He took a B.S. degree at Duke University in 1932, went to Western Reserve University in 1935 and took his Ph.D. there in 1938. In 1944 Pillemer worked at the Army Medical School in Washington. When he returned to Western Reserve University he became, in quick succession, associate professor of immunochemistry (1946) and professor of biochemistry (1950) without teaching duties at the Institute of Pathology.

His association with W. A. Perlzweig at Duke University, with E. E. Ecker, who was his chief at Western Reserve University for many years, and with E. J. Cohn at Harvard, undoubtedly influenced his experimental approach and orientation, but the direction and drive of his endeavours flowed from his own stormy and original personality and from the intuitive faculties of his mind. When one came to know him intimately, one realized the uncompromisingly high standards of values which guided his scientific decisions and the tremendous emotional strain caused by the demands he so pitilessly made on himself.

Pillemer's experimental work ranged from studies of protein specificity[1] and complement[2] to clinical biochemistry[3] and to the purification of toxins and toxoids[4].

Pillemer made contributions of fundamental significance in several directions, but his choice of research projects was usually strongly weighted by their potential practical value. Purification studies were aimed at an improved combined vaccine of diphtheria–tetanus–pertussis; the later development of a pertussis vaccine by ultrasonic disintegration of the microbes followed by absorption of the protective antigen on human red cell stroma continued this endeavour[5].

During recent years he abandoned other lines of research to turn his attention again to complement; soon 'Properdin' was discovered by him and his small band of enthusiastic and able colleagues and assistants. 'Properdin', acting with components of complement and magnesium ions, was shown to be part of the constitutive defence mechanisms of the mammalian organism and to mediate the destruction of certain micro-organisms and abnormal red cells[6]. By the time of Pillemer's death, it was clear that the discovery of 'Properdin' represented an important milestone in the study of the non-induced defence mechanisms against infection.

Pillemer felt that the highest award a scientist could gain was respect of his colleagues for his work—he certainly gained this award.

Our sympathy goes to his family. He leaves a wife, who as Jean Burrell[7] was among his collaborators, and four sons. Bernhard Cinader

NEWS and VIEWS

Hydraulics Research :
Sir Claude Inglis, C.I.E., F.R.S.

Sir Claude Inglis is retiring from the post of director of the Hydraulics Research Organization of the Department of Scientific and Industrial Research. According to "Who's Who", Sir Claude was born in 1883 ; those who are familiar with him and with his work will read this statement with some incredulity, for it implies that at the date of his appointment as the first director of the Organization he was already some sixty-three years of age. Although so many fundamental contributions to the subject of hydraulic scale models had been made by British engineers (notably Osborne Reynolds and A. H. Gibson), facilities for such investigations, especially in the field of loose-boundary hydraulics, then lagged far behind those established in many places abroad. Happily, the situation is now different, and this is very largely due to Sir Claude's quiet but effective persistence, his infinite patience and his capacity for continuous hard work ; all combined with his specialized knowledge and the experience of his earlier directorship of the Indian Waterways Experiment Station at Poona. The Department of Scientific and Industrial Research now has a magnificent Hydraulics Research Station at Wallingford (a site chosen by Inglis), which includes a main experimental hall with a floor area of 60,000 sq. ft. Before joining the Department, Sir Claude had comparatively little experience of tidal models ; nevertheless, he has since directed several notable tidal model investigations of considerable complexity. A remarkable feature of his directorship has been his enthusiasm for the development of new measuring devices, the design of novel tide- and wave-making machinery and the exploitation of radioactive isotopes as an aid in tracing the movement of sand and silt. At the same time, he has maintained his interest in the basic mechanics of the regime of channels and the meandering of rivers.

Mr. Fergus H. Allen

Mr. Fergus H. Allen, who has been appointed to succeed Sir Claude Inglis as director of the Hydraulics Research Station at Wallingford, has earned widespread respect and confidence during tenure of the office of assistant director. The site of the Station was only acquired in 1949, and the design and construction of buildings and equipment there have clearly demanded strenuous efforts by all concerned and not least by Mr. Allen, who has shared the responsibility for many of the investigations undertaken both at the Station itself and on other premises, and has at the same time shouldered many of the administrative duties. Mr. Allen has visited hydraulics research laboratories abroad and has been the author or co-author of several publications, including "The Regimen of the Thames Estuary as affected by Currents, Salinities and River Flow", a paper which aroused considerable discussion when it was read by Inglis and Allen at the Institution of Civil Engineers in May 1957. At meetings of the Hydraulics Research Board of the Department of Scientific and Industrial Research and at conferences held by bodies such as the International Association for Hydraulic Research and the Permanent International Association of Navigation Congresses, Mr. Allen has made a very favourable impression by his grasp of the subjects under discussion and by his capacity for lucid exposition. The Hydraulics Research Station may look forward with confidence to continuing progress under his direction.

Irrigation Research Station, Griffith :
Mr. E. R. Hoare

Mr. E. R. Hoare has been appointed as officer-in-charge of the Commonwealth Scientific and Industrial Research Organization, Irrigation Research Station, Griffith, New South Wales. Mr. Hoare comes from the United Kingdom Institute of Agricultural Engineering, Silsoe, Bedfordshire. He has been in charge of the Horticultural Engineering Department, which has made important contributions to research on plant cultivation. He graduated in mechanical and electrical engineering at the University of London in 1934. For eleven years he was research engineer and physicist with the General Post Office. He undertook important services for the Armed Forces during the War, including the synchronization of all radar stations on the east coast of Britain, and the design and installation of D-day cross-channel communications.

Mr. Hoare has applied his experience as a radio and electrical engineer to the study of the basic requirements of the growing plant. In this work he and his team of research workers have developed many original and sensitive electronic instruments for assessing such factors as the respiration of plants and their sensitivity to light and heat. Among the projects successfully developed by the Horticultural Engineering Department under his guidance have been the study of the uptake of water in plants both in glasshouse and open ground cultivation ; cultivation and tractor problems ; plant-culture under glass with special reference to heat requirements ; crop- and pest-spraying problems ; study of light, radiant energy and radioactivity in relation to plant growth.

Giovanni Alfonso Borelli (1608–79)

Mathematician, astronomer, physicist and physiologist, Giovanni Alfonso Borelli was the son of a soldier and was born at Naples 350 years ago on January 28, 1608. A pupil of Galileo, he became professor of mathematics at Messina in 1649 and seven years later, at the invitation of Ferdinand II, Duke of Tuscany, went to Pisa. There he met Malpighi, whom he taught mathematics and physics and from whom he acquired an interest in physiology. Borelli looked upon locomotion, respiration and digestion as mechanical processes, describing digestion as the result of a mechanical trituration of the food within the stomach. He taught, erroneously, that contracting muscle increases in bulk due to fermentation in muscle, and believed that the nerve supplying the muscle discharged a fluid, *succus nerveus*—his substitute for Galen's 'animal spirits'. His neurogenic theory of the heart beat, revived by J. J. C. Legallois in 1812, held the field against the myogenic theory until modern times. Borelli's "De motu animalium", an enormous work in two volumes, was published posthumously in 1680–81. His pseudonymous letter, "Del movimento della cometa apparsa il mese di decembre 1664" (1665), contains the first suggestion of a parabolic path, and his "Theorica mediceorum planetarum ex causis physicis deducta" (1666) deals with the influence of attraction on the satellites of Jupiter. In 1679 he invented a diving apparatus capable of altering the specific gravity of the diver. Borelli returned to Messina in 1668 and in 1674 retired to Rome, where he lived under the protection of Queen Christina of Sweden. A morose, obstinate and quarrelsome man, he died of pleurisy on December 31, 1679.

The Commonwealth Trans-Antarctic Expedition

THE trans-Antarctic survey party led by Dr. Vivian Fuchs reached the South Pole on January 20, where they were met by Sir Edmund Hillary and Rear-Admiral G. Dufek, commander of the American naval base at the Pole. The expedition, which consists of Dr. Fuchs and his team of eleven men, four 'Snocats' and a 'Weasel', with two dog teams and sledges, left Shackleton Base for South Ice on the Weddell Sea on November 24 and started from South Ice for the Pole on December 21. Throughout the journey the expedition has conducted a programme of scientific observations including seismic soundings every thirty miles, gravimetric readings every fifteen miles and meteorological observations every three hours, in connexion with the International Geophysical Year. It is reported that Dr. Fuchs proposes to continue his journey across the Antarctic continent to Scott Base on the Ross Sea using the depots of food and fuel established by Sir Edmund Hillary's earlier supporting party.

Tenth Anniversary of British Ocean Weather Ships

IN August 1957 British ocean weather ships completed ten years of service in the North Atlantic. The first, *Weather Observer*, arrived at station 'Juliett' (53° 50′ N., 18° 40′ W.) on August 5, 1947, and transmitted her first observation to the Central Forecast Office, Dunstable, on that day, thereby inaugurating the active participation of the United Kingdom in the North Atlantic Station Agreement. The record of the ten years work is summarized by Comdr. C. E. N. Frankcom, marine superintendent of the Meteorological Office, in an article in the issue of the *Meteorological Magazine* of October 1957. Besides the usual surface observations, regular upper air ascents with radio-sonde and radar-wind balloons have been made, a difficult task in the high winds so often encountered at the ocean weather stations.

In addition to performing their meteorological work, the four ships have provided navigational assistance to aircraft, carried out oceanographic research, and been used for researches by other institutions, for example, in seismological work by the University of Cambridge. Ten of the marine staff have served throughout the decade and one meteorologist for six years. The ships employed, converted "Flower"-class naval corvettes, are showing wear after their war and ocean-station work and one of them is to be replaced by a larger "Castle"-class frigate now being converted for its new duties. The new vessel, which may be followed by others of the same type, will be much more roomy and comfortable.

U.S. National Astronomical Observatory

THE National Science Foundation has entered into a contract with the Association of Universities for Research in Astronomy, Inc., for the construction, operation and maintenance of a U.S. national astronomical observatory. The Association, which has its principal office in Phoenix, Arizona, comprises the following Universities: California, Chicago, Harvard, Indiana, Michigan, Ohio State and Wisconsin. These Universities joined together to constitute a management group for the new observatory, because they have had experience in operating large observatories and have big programmes of research and graduate instruction in astronomy. As the project develops, it is expected that other universities and individuals will join the Association. The Board of Directors of the newly formed corporation consists of a scientific and an administrative representative of each of the seven participating universities, as follows: *California:* Dr. C. D. Shane, director, Lick Observatory; Mr. J. M. Miller, assistant vice-president, business affairs; *Chicago:* Dr. G. P. Kuiper, director, Yerkes Observatory; Mr. W. B. Harrell, vice-president, business affairs; *Harvard:* Dr. D. H. Menzel, director, Harvard College Observatory; Mr. Edward Reynolds, administrative vice-president; *Indiana:* Dr. F. K. Edmondson, chairman, Department of Astronomy; Mr. J. A. Franklin, vice-president and treasurer; *Michigan:* Dr. R. R. McMath, director, McMath–Hulbert Observatory; Mr. G. L. Lee, jun., controller; *Ohio State:* Dr. P. C. Keenan, professor of astronomy; Mr. C. F. Miller, controller; *Wisconsin:* Dr. A. E. Whitford, director, Washburn Observatory; Mr. A. W. Peterson, vice-president. The corporation appointed Dr. McMath president, Dr. Edmonson as vice-president, and Mr. J. M. Miller as secretary.

The new observatory, when completed, will be open for research to all qualified astronomers. Under the terms of the contract, it is hoped to equip the Observatory initially with a 36-in. and an 80-in. telescope. The National Science Foundation's appropriation for the fiscal year 1958 includes an item of 3·1 million dollars for construction of an optical observatory on a site which is to be selected as a result of extensive tests. The Foundation earlier awarded grants totalling approximately 800,000 dollars to the University of Michigan to support studies leading to the establishment of such an observatory (see *Nature*, 178, 837; 1956). After extensive studies under the direction of Dr. Aden B. Meinel, executive secretary of the Foundation's advisory panel for the observatory, the choice of site was narrowed to five locations: Kitt Peak (6,875 ft.), 40 miles south-west of Tucson, Arizona; Summit Mountain (7,500 ft.), 11 miles south of Williams; Chevalon Butte (6,950 ft.), 40 miles south of Winslow; the Hualapai Mountains (7,350 ft.), 13 miles south of Kingman; and Junipero Serra (5,800 ft.), 21 miles west of King City, California. A special committee, under the chairmanship of Dr. C. D. Shane, director of Lick Observatory, recently spent some time in Arizona reviewing the situation. As a result, site studies will be continued at Kitt Peak and Hualapai and at a new location on Mormon Mountain (8,440 ft.), 35 miles south of Flagstaff, but discontinued elsewhere because recent work has shown that the other sites are unsuitable. Temperature and wind velocity will continue to be measured and seeing conditions tested at the three remaining sites. Studies are expected to be completed by about June 30, 1958.

British Group for Computation and Automatic Control

THE British Conference on Automation and Computation is being organized in three sections, as follows: (*A*) the British Group for the Engineering Applications of Automation; (*B*) the British Group for Computation and Automatic Control; and (*C*) the

British Group for the Sociological and Economic Aspects of Automation Techniques (*Nature*, 179, 948; 1957). At a meeting held on December 20, Group *B*, the British Group for Computation and Automatic Control, was formally constituted, comprising as its members twenty-three professional and learned institutes and societies with interests in these fields.

The objects of the Group are to foster the development and applications of automatic controls, computing and data-processing equipment and programming techniques; to afford a common meeting ground for the adhering organizations; to maintain liaison with other Groups of the British Conference on Automation and Computation and with corresponding national committees of other countries; and to encourage and co-ordinate the presentation at international conferences of British papers on subjects falling within the purview of the Group. Mr. T. E. Goldup (president of the Institution of Electrical Engineers) was elected chairman of the Group, with Messrs. J. F. Coales (Society of Instrument Technology) and E. M. Renals (Institute of Cost and Works Accountants) as vice-chairmen. Mr. J. D. Green (Institute of Chartered Accountants in England and Wales) was elected honorary treasurer, and Mr. W. Bamford (Institution of Electrical Engineers) honorary secretary, and the offer of the Institution of Electrical Engineers to provide secretarial services for the Group was accepted. The chairman, the honorary secretary and one vice-chairman (Mr. E. M. Renals) were chosen to act as the representatives of the Group on the general committee of the British Conference on Automation and Computation, which will also comprise representatives of the two remaining Groups now in process of formation. The constitution of the Group provides for the election of additional member societies: those interested should communicate with the honorary secretary of the Group, at the Institution of Electrical Engineers, Savoy Place, London, W.C.2.

Transparent Magnetic Oxides

The work going on in Prof. L. Néel's laboratory in Grenoble on ferrimagnetism in rare earth iron garnets has recently been extended in the Bell Telephone Laboratories by an investigation of their optical resonance behaviour carried out by J. F. Dillon, jun., using single crystals grown by J. W. Nielsen. These materials are remarkable in that some of them are transparent. Consequently, their Faraday rotation can be conveniently investigated, and it is found that it amounts to several degrees per mil of thickness, so that domains within the crystals can be made clearly visible, enabling the domain structure to be studied over a wide range of temperature and field conditions. Yttrium iron garnet has been most completely studied so far. It has a Curie temperature of 545° K. and a spontaneous magnetization, at 0° K. and infinite field, of 4·96 Bohr magnetons per molecule, which is close to the theoretical value of 5·0. This magnetization results from super-exchange interactions through the O^{2-} ions between Fe^{3+} ions in crystallographically different positions in the cubic lattice. The fact that yttrium iron garnet contains magnetic ions with but a single valence is of great interest, and X-ray and neutron-diffraction studies have shown that, unlike the ferrites, interactions between identical magnetic ions wholly occupying two different crystallographic sites are responsible for ferrimagnetism in the garnet structure.

Systematics and Biology of Ungulates

About sixty zoologists from Belgium, Denmark, France, Germany, Great Britain, Holland, Italy, Russia, Switzerland and the United States, attended a three-day colloquium in Paris on the "Systematics and Biology of the Ungulates" during October 23–26. The colloquium was arranged by the Comité de Direction et d'Administration of the journal *Mammalia* and the (Benelux) Société pour l'étude et la protection des mammifères, under the presidency of Prof. E. Bourdelle, with Prof. Roger Heim as président d'honneur, and Dr. Jean Dorst as secretary-general. After a reception at the Parc zoologique de Vincennes on the evening of October 23, the following three days were fully occupied in the presentation and discussion of some thirty papers embracing many aspects of the subject from classification and conservation to blood groups, placental structure, animal behaviour, and the biology of particular species. The text of these papers, together with some others the authors of which were unable to be present at the colloquium, will be published in full in *Mammalia*. The members of the colloquium agreed, as was plain from the speeches at the concluding dinner where they were the guests of the management of *Mammalia*, that the meeting was most valuable and stimulating not only in its formal business but equally in the opportunity it gave to zoologists working on the Mammalia for informal discussion and exchange of ideas. It is greatly to be hoped that organizations in other countries will follow the example set by their colleagues of France, and will arrange similar international meetings for the benefit of zoologists interested in the study of the Mammalia.

Cytological Techniques and the Apical Meristem

The reactivity of the shoot apical meristem as ascertained by cytological and other techniques, in particular by French observers led by Plantefol and Buvat, has been discussed by Wardlaw (*New Phytol.*, 56, 221; 1957). The French school places great emphasis on the initial or meristematic ring as the active region of the apical meristem, particularly in the inception of leaf primordia and phyllotaxis. The conclusion reached in the paper under consideration is that the cytological investigations now being so vigorously pursued by the French workers and their adherents are to be welcomed as contributing new facts about the distribution of nuclear and cytoplasmic proteins in different regions of the apex; and it should be recognized that the theories and ideas which have been expounded, whether or not they are validated by further work, have given a new impetus and direction to the study of the shoot apex. The results that have so far accrued from this approach, however, tend to forfeit some of their value and objectivity, partly because of the *a priori* complete acceptance and, indeed, over-emphasis, on the part of the protagonists and their followers, of the validity of the underlying theory of phyllotaxis and apical organization, with a consequential tendency for the observations to be somewhat selective in character, and partly because the new observations have not been related to the well-substantiated body of evidence on apical ontogeny, organization and reactivity that has accrued from experimental and other investigations. Lastly, in considering the views of the French workers and criticisms of these views, it is well to bear in mind how very little is yet known about the physiology and biochemistry of the apex.

College

New facts, however, can be sought and they may decide the controversial issues.

Peaceful Uses of Atomic Energy

A MAJOR symposium on the peaceful uses of atomic energy will be held in Sydney during June 2–6. The symposium is being sponsored by representatives of the universities, professional institutes, industrial firms, power authorities, Commonwealth and State departments and the Australian Atomic Energy Commission. The symposium will be a forum for the discussion of technical and scientific aspects of the peaceful uses of atomic energy. Papers will be presented by overseas scientists as well as many Australian contributors. Particular attention will be given to the part atomic energy can play in the development of Australia. There will be several public lectures and a special atomic energy exhibition, to show developments in uranium mining, research into nuclear power and the industrial uses of radioactive isotopes. Further information can be obtained from the Symposium General Secretary, A.A.E.C. Research Establishment, Private Mail Bag, Sutherland, New South Wales, Australia.

University News: London

DR. F. G. FOSTER, lecturer in statistics in the London School of Economics and Political Science, has been appointed to the University readership in statistical computing tenable at that School.

Manchester

THE board of Unilever has given to the Manchester College of Science and Technology £21,000 under a seven-year deed of covenant. Out of this, £2,000 is to be allocated to the staff college, the balance to be divided equally between the Chemistry and Chemical Engineering Departments.

Announcements

A DISCUSSION on "Experimental Results with the ZETA Apparatus on Controlled Thermonuclear Reactions" will be opened by Sir John Cockcroft in the rooms of the Royal Society on February 5 at 3 p.m.

MR. JOHN BUNYAN, Leverhulme Research Fellow, St. Mary's Hospital Medical School, Paddington, has been elected president of the Royal Microscopical Society; he will hold office for two years.

THE Medal of the New York Academy of Medicine has been awarded to Dr. Alphonse R. Dochez for his distinguished service in medicine. After graduation from the Johns Hopkins Medical School, Dr. Dochez was appointed to the staff of the Rockefeller Institute, where, with Gillespie, he established the biological classification of pneumococci into specific types. During the First World War, Dr. Dochez worked on the serological differentiation of hæmolytic streptococci causing respiratory diseases, and later devoted some years to virus studies of the common cold.

MR. LEWIS T. WRIGHT, general secretary of the Amalgamated Weavers' Association, has been appointed to the Council for Scientific and Industrial Research in succession to Mr. W. L. Heywood, who has been appointed a member of the Restrictive Practices Court. Mr. Wright is chairman of both the Production and Scientific Advisory Committees of the Trades Union Congress and is also chairman of the British Productivity Council.

DR. M. E. FOSS has been appointed head of the Department of Chemistry and Metallurgy, Coventry Technical College, in succession to Dr. H. C. Smith, who has been relieved of that office in order to take up the full-time post of vice-principal of the College, of which he has been deputy-principal for the past five years. Dr. Foss, who is vice-chairman of the Bristol Section of the Royal Institute of Chemistry, was senior lecturer in organic chemistry at Gloucester Technical College where he had been on the staff for six years. Prior to that he was lecturer in biochemistry at Guy's Hospital Medical School.

THE sixty-third annual congress of the South-Eastern Union of Scientific Societies will be held in Reading, meeting in the University of Reading, during April 9–11. The president-elect is Prof. H. L. Hawkins. Further information can be obtained from the hon. local secretary, Mrs. A. Hasker, Clarence Lodge, 93 London Road, Reading.

THE Metal Physics Committee of the Institute of Metals is organizing a one-day symposium on "Metallurgical Aspects of Semi-Conductors", to be held on February 25 at the College of Technology, Gosta Green, Birmingham. Further information can be obtained from the Secretary, Institute of Metals, 17 Belgrave Square, London, S.W.1.

THE annual general meeting of Aslib (Scottish Branch) will be held on February 7 in the Scottish Central Library, Lawnmarket, Edinburgh. The chairman will be Dr. W. M. Cumming, and there will be lectures on "United States Information Services to Industry in the United Kingdom" by Miss Margaret Haferd, and "Scientific Information in the Modern World" by Dr. J. C. Malloch. In the afternoon there will be a symposium on "Librarians Here and There".

THE second Australian Conference in Radiation Biology will be held at the Cancer Institute, Melbourne, Australia, during December 15–19. Papers on relevant subjects are invited, and titles and a 250-word abstract should be in the hands of the convener by July 31. Further information can be obtained from Dr. J. H. Martin, Physics Department, Cancer Institute Board, 483 Lt. Lonsdale Street, Melbourne, Victoria, Australia.

THE Ministry of Agriculture, Fisheries and Food is offering the following scholarships for rural workers, or to the sons and daughters of rural workers, of seventeen years of age or more: twenty senior scholarships tenable at universities or colleges, for degree or diploma courses in an agricultural subject or in veterinary science; and thirty junior scholarships, with six extensions for existing holders, tenable at farm institutes for one-year courses in agriculture, horticulture, dairying or poultry husbandry.

Further details and application forms (to be completed by February 28) may be obtained from the Secretary, Ministry of Agriculture, Fisheries and Food, Great Westminster House, Horseferry Road, London, S.W.1, or from education offices of County Councils.

THE International Council of Scientific Unions Secretariat has removed to a new address at Paleis Noordeine, The Hague, Netherlands.

ERRATUM. In the communication entitled "Antimitotic Activity of 5-Tertiary Butyl Benzimidazolone" in *Nature* of December 21, p. 1428, from paragraph 3 onwards, for "5-tertiary benzyl benzimidazolone" read "5-tertiary butyl benzimidazolone".

NEWER PREPARATIVE METHODS IN ORGANIC CHEMISTRY

A SYMPOSIUM was held jointly by the Chemical Society and the Fine Chemicals Group of the Society of Chemical Industry on "Newer Preparative Methods in Organic Chemistry" at the Chemistry Department, University College, London, on November 7. The meeting took the form of two sessions in the afternoon at each of which three papers were read; the reading of papers was followed by a dinner in the evening, also at University College. The afternoon meetings were attended by nearly 400 chemists and the evening dinner by 116. Papers were read on "Dehydrogenation with Manganese Dioxide" by Dr. R. M. Evans, "Amine Oxidations" by Prof. H. B. Henbest, "Organic Oxidations with Hexavalent Chromium" by Dr. R. Slack, "Mixed Anhydrides as Synthetical Reagents" by Prof. G. W. Kenner, "Some Reactions between Metal Carbonyls and Acetylenic Compounds" by Dr. M. C. Whiting and "Some Applications of Metal Carbonyls in Organic Chemistry" by Dr. P. O. Lenel.

The meeting was opened by Prof. E. L. Hirst, who mentioned that this was the first joint meeting between the Chemical Society and the Fine Chemicals Group and expressed his hope that it would be a successful one. Dr. B. A. Hems took the chair at the first session and Prof. E. R. H. Jones presided over the second.

The purpose of the meeting was to discuss the applications of some reagents that have recently come into prominence in preparative chemistry and of which the scope and details of experimental methods may not yet be widely known. The authors of the papers had themselves had extensive personal experience of these reagents and could point to the theoretical and practical significance of various methods of using them.

Dehydrogenation by manganese dioxide was discussed by Dr. Evans. When this reagent is used for dehydrogenation the method of preparation and the physical form of the oxide appear to have a considerable effect on its reactivity. One form, prepared under strongly alkaline conditions, appears to be the best for dehydrogenating unsaturated primary or secondary alcohols to $\alpha:\beta$-unsaturated aldehydes or ketones, whereas an acidic form appears to be better for dehydrogenating unsaturated ketones, at least in the sterol group. Dr. Evans pointed out that manganese dioxide brought about many other oxidizing reactions under more vigorous conditions, but that selectivity was then lost. The most useful applications of this reagent lay with specially active forms of the oxide used in mild conditions on polyene or polyenyne alcohols that were difficult to oxidize to the corresponding aldehydes or ketones by other methods.

The dehydrogenation of amines to give unsaturated compounds was discovered many years ago but has received very little application in general preparative chemistry. It is to be expected that the work that Prof. Henbest and his colleagues are doing on the subject will bring this potentially useful reaction to the notice of a wider audience.

He mentioned in his paper that tertiary amines are generally regarded as being chemically rather unreactive, but pointed out that this is not so. Dehydrogenation with mercuric acetate under mild conditions in dilute acetic acid gives enamines. Sometimes in a heterocyclic ring system complete dehydrogenation to the aromatic ring will take place, but often partial dehydrogenation can also occur. He compared this with the action of manganese dioxide on tertiary amines, where again enamines are formed under mild conditions, but this is often accompanied or followed by oxidative cleavage of the double bond to give amides. Diethylaniline gives a mixture of ethylvinyl aniline and ethylformanilide.

The third of the oxidizing agents discussed, chromic oxide, is, of course, widely used for a variety of purposes. It may be applied to both dehydrogenations and oxidations by a diversity of methods the theoretical and practical significance of which is not yet thoroughly understood. Differences undoubtedly exist about the effectiveness with which these different techniques can be used on different substrates, and although it is probable that a common theoretical background exists, it is nevertheless true that much has yet to be learnt about the best method to be used on any particular type of substance. Dr. Slack pointed out that oxidations with chromic oxide in acetic acid were often not stoichiometric, that chromic oxide could still remain, even in the presence of unoxidized substrate, because its oxidizing action was inhibited by the presence of lower valency forms of chromium. He added that one function of the sulphuric acid, sometimes added to these reactions, is to overcome this inhibition. He compared the uses of chromic oxide as its pyridine complex or tertiary butyl ester and finally pointed to the existence of some other hexa- and penta-valent chromium complexes such as acetyl chromic acids or complex salts derived from trichloro oxo-chromium (V) that had not yet been investigated by organic chemists but might repay some attention.

These three papers composed the first session of the meeting and were followed by three on condensation reagents.

Mixed anhydrides have come very much into prominence during the past few years for condensations involving carboxyl groups where, because of the delicacy of either the starting materials or the final product, mild reaction conditions are required.

Another advantage that mixed anhydrides have is that one of the partners is usually derived from a small and relatively cheap molecule, and their use avoids the wasteful regeneration of a molecule of the larger and perhaps much less accessible acid. Prof. Kenner pointed out that in a mixed anhydride a cleavage reaction could theoretically take either of two directions and he discussed the relative activities of various groups showing that the attack of a nucleophilic reagent was determined by the relative electrophilic character of the two parts of the anhydride. This, however, was not the only factor affecting reaction; the pK of the acids taking part, steric hindrance and the co-ordination number at the electrophilic centres also played a part in determining which of the two reaction products would predominate. Mixed anhydrides derived from chloroformic ester, phosphoric and sulphuric acids or their esters had shown themselves to be extremely useful in the synthesis of peptides and nucleosides.

The last two papers were on metal carbonyls. Frequently to-day, new preparative methods involve the use of reagents that a few years ago were considered too difficult or too dangerous to handle because of the risks of explosion, fire or toxicity. The hazards of using acetylene under pressure and the toxicity of carbonyls frequently cause these reagents to be avoided and it is hoped that these papers, in which safe methods of handling were discussed by the authors, may alleviate some of these fears.

Dr. Whiting stressed the usefulness of nickel carbonyl in reacting with acetylenes having a terminal triple bond to give α-substituted acrylic acids, a type of compound otherwise rather inaccessible. These reactions are carried out in acetic acid at moderate temperature, with excess carbonyl which is not difficult to handle provided that its transfer from vessel to vessel is carried out under conditions involving only a very slight degree of exposure to air, and provided that excess is removed from the reaction mixture by co-distillation with ether. The distillate is immediately disposed of and leaves a reaction mixture that can safely be handled in the usual way. Even so, both he and Dr. Lenel pointed out that although these substances could be handled safely they still had to be treated with considerable respect. Dr. Whiting also went at some length into the mechanisms of these reactions. He was followed by Dr. Lenel, who dealt mostly with the industrial applications of carbonyls in reaction with acetylenes to give unsaturated acids, or with olefines to give saturated acids. Cobalt carbonyl catalyses the important reaction of carbon monoxide and hydrogen with olefines to give aldehydes which can then be reduced to alcohols by hydrogenation. The industrial preparation of alcohols and acids by these reactions is now carried out on a very large scale involving many thousands of tons of product per annum, though the reactions necessitate fairly high temperatures and pressures. Several other carbonyls of transitional elements are known, though they have not yet achieved prominence in an industrial sense; they are of profound interest to the inorganic and theoretical chemist because their constitutions throw new light on electronic structures.

This was, as Prof. Hirst pointed out, the first joint meeting of the Chemical Society and the Fine Chemicals Group of the Society of Chemical Industry, and it is very much to be hoped that it will be followed by others. The members of the Fine Chemicals Group are predominantly interested in the preparation of complex chemicals in a high degree of purity: perfumes, photographic sensitizers, drugs, vitamins and hormones, for example. These processes often involve twelve to twenty stages that, if they are to be carried out efficiently, demand the use of the most up-to-date knowledge and techniques available. This Group, of all the special groups in the Society of Chemical Industry, is the one that has the strongest kinship with the Chemical Society. With the rapidly increasing activity in industrial chemistry of all kinds and the rapid extension of industrial technical staffs, joint meetings of this kind can be a valuable aid to progress. A closer relationship between the members of the two Societies can be of great benefit to both.

INTERACTION IN IONIC SOLUTIONS

THE Faraday Society held a general discussion on "Interaction in Ionic Solutions" at Oxford during September 17–19. The meeting was held in the University Laboratory of Physiology, and more than 180 members and visitors stayed in Balliol College, where the guest-night dinner was held. The president of the Society, Mr. R. P. Bell, in opening the discussion, reminded those present that a general discussion on "Electrolyte Solutions" had been held thirty years ago in Oxford. In fact, the president's first published contribution to the subject was presented at that meeting in 1927 in a joint paper with Sir Harold Hartley. Among others present, who had attended and contributed to the earlier discussion, was Prof. H. S. Harned (Yale), who delivered the Spiers Memorial Lecture on "Some Recent Experimental Studies of Diffusion in Liquid Systems". Prof. Harned gave an account of the elegant experimental techniques for the precision measurement of diffusion in electrolytes which have been recently developed at Yale, and indicated some of the many possible directions of further advance. The accurate determination of activity coefficients by diffusion measurements is a remarkable achievement.

The first paper to be discussed was that by Prof. H. Falkenhagen and Dr. G. Kelbg (Rostock), which dealt with the extension of the limiting-law equations. Dr. M. Eigen (Göttingen) directed attention to the information that can be obtained about the intimate details of short-range interaction in bi-bivalent electrolytes by the observations of relaxation effects in sound-absorption spectra. Dr. S. Levine and Mr. H. E. Wrigley (Manchester) reported a calculation of the interaction of two univalent ions at small separations, and considered the relevance of the macroscopic dielectric constant of the solvent in this situation. In discussion, Prof. L. Onsager (Yale) directed attention to some recent mathematical advances which might help in the electrolyte problem, while Prof. H. S. Frank (Pittsburgh) seized the opportunity to express heretical views about the Debye–Hückel theory. A paper by Prof. T. F. Young, Mr. Y. C. Wu and Dr. A. A. Krawetz (Chicago) reported some measurements of the heat effects due to interactions between ions of like charge when pairs of univalent electrolytes with an anion or cation in common are mixed.

There followed a major section devoted to the presentation and discussion of papers dealing with the incomplete-dissociation model as a way of handling short-range ion–ion interactions. Prof. C. W. Davies (Aberystwyth) surveyed the present position in an introductory paper. Prof. E. A. Guggenheim (Reading) considered the ion distribution in dilute aqueous solutions of single binary electrolytes, and concluded that although the Debye–Hückel approximation is invalid for bi-bivalent sulphates in water, the model (complete ionization to rigid spherical ions) is satisfactory if, following N. Bjerrum, ions of opposite charge approaching more closely than 10–14 A. are treated as associated. Dr. O. Redlich and Dr. G. C. Hood (Shell Development Co., California) presented the results of Raman and nuclear magnetic-resonance investigations of the dissociation of strong acids (including nitric, perchloric and sulphuric acids). The agreement between the results is very satisfactory. Mr. W. D. Bale, Mr. E. W. Davies, Mr. D. B. Morgans and Dr. C. B. Monk (Aberystwyth) reported on the study of various ion association equilibria by spectrophotometry. Mr. W. G. Davies, Mr. R. J. Otter and Dr. J. E. Prue (Reading) reported precise spectrophotometric results for copper sulphate solutions, and discussed the significance of the dissociation constants obtained from cryoscopic, conductimetric and spectrophotometric measurements. Dr. G. H. Nancollas (Glasgow) gave an account of attempts to obtain and interpret heat and entropy changes for ion association reactions. In the discussion of this section there was general agreement about the validity and usefulness of the incomplete dissociation model for higher-valent electrolytes, but there was some dissension, particularly between Prof. Davies and Dr. Prue, about the relation of the numerical values of the dissociation constants to the choice of a distance of closest approach of free ions.

A section on ion-solvent interaction was introduced by Prof. H. S. Frank and Dr. Wen-Yang Wen (Pittsburgh), who discussed the several ways in which they consider ions affect the structure of water. Dr. O. T. Samoilov (Moscow) had submitted a paper on "A New Approach to the Study of Hydration of Ions", but was unfortunately absent. Dr. S. R. Gupta, Dr. G. J. Hills (Imperial College) and Dr. D. J. G. Ives (Birkbeck College) considered that their recent very precise measurements of activity coefficients of aqueous hydrochloric acid solutions over a temperature-range provide evidence for changes in heat capacity which can be interpreted in terms of changing ion-solvent interactions. A theoretical paper by Dr. A. D. Buckingham (Oxford) led to the conclusion that the ion-quadrupole term is significant in the interaction between the ion and solvent molecule, and that the dielectric-saturation effect is unimportant outside the first hydration sphere.

Few real advances or firm conclusions were discernible in the ion-solvent interaction section. However, there is considerable evidence for the existence of the proton as a tetrahydrate in water. It is entirely reasonable that a hydroxonium ion forms strong hydrogen bonds with three neighbouring water molecules and Dr. K. N. Bascombe and Mr. R. P. Bell (Oxford) showed that the variation of Hammett acidity functions with concentration in concentrated strong acids can be satisfactorily interpreted with such a model. Their general conclusion was supported by Dr. Th. Ackermann's (Hamburg) study of the heat capacity and infra-red absorption spectra of aqueous acid and alkali solutions. Further support was provided by the X-ray diffraction studies of aqueous electrolyte solutions by Mr. C. L. van Panthaleon van Eck, Mr. H. Mendel and Mr. W. Boog (Royal Dutch Shell, Amsterdam). This method shows considerable promise as a direct way of exploring the solvation problem; present results suggest that water molecules in water and potassium and calcium ions are octahedrally surrounded by six water molecules.

Dr. P. A. H. Wyatt (Sheffield) considered the interpretation of acidity functions in concentrated acids. Dr. M. Kaminsky (Marburg) discussed the relationship between the dependence on temperature of viscosity of aqueous solutions and the ion-solvent interaction. A paper on the dependence on concentration of the surface potentials of a number of electrolyte solutions by Dr. J. E. B. Randles (Birmingham) suggested that the interpretation of the results is too complex to lead to reliable evidence about ion hydration. Mr. M. Smith and Dr. M. C. R. Symons (Southampton) presented a study and interpretation of the effects of changes of solvent, added electrolyte and temperature on the first electronic absorption band of the iodide ion.

REORGANIZATION OF THE METEOROLOGICAL OFFICE

In 1955, the Secretary of State for Air appointed a Committee under Lord Brabazon to review the organization of the Meteorological Office. This Committee took evidence from users, both inside and outside Government service, of the services provided by the Meteorological Office, and from members of the Office staff. The main features of the Committee's report, which will not be published, were given to the House of Commons in June by the Minister for Air.

The Committee agreed that the Air Ministry should continue to be responsible for the Meteorological Office, and expressed the opinions that the standing of the Office as a scientific institution is high and that users have considerable confidence in the services provided for them. In considering possible lines of advance the Committee singled out the development of numerical methods of forecasting as one of the most important, welcomed the forthcoming installation of an electronic computer in the Office, and suggested there was a possibility of achieving greater precision in local forecasting by a closer study of weather characteristics and by the use of the radar-echo method of observing cloud and precipitation.

As regards internal arrangement, the Committee recommended that the Office should be reorganized into three 'prongs' dealing, respectively, with forecasting and services, research, and administration. This reorganization was put into force in July 1957. Its recommendations also led to a regrading of the senior posts whereby the post of Director has been raised to that of Director-General, the forecasting and services 'prong' is placed under the Director of Services and research under the Director of Research, each of the two latter posts being in the grade of chief scientific officer. The administrative 'prong' now under an assistant secretary has been enlarged to make the Office more self-contained in administrative matters.

Several new posts in the grade of senior principal scientific officer have also been created, and the number of the highest posts available to members of the experimental officer class will also be increased. These measures will improve the career prospects, a matter on which the Brabazon Committee expressed considerable concern, for all classes of the staff. The need for improvement was especially evident in the scientific officer class, to which it had been difficult to attract recruits of sufficiently high ability.

On the Services side the new posts include a senior principal scientific officer to control 'Techniques and

Training' with the special task of ensuring close contact between research and forecasting.

Another new post in the same grade, responsible direct to the Director-General, has been established to co-ordinate the increasingly large volume of work in international meteorological relationships.

In considering research the Brabazon Committee paid tribute to the work of the Meteorological Research Committee which, established in 1942, has had an outstanding success. The Director-General expressed in his article the gratitude of the Office to the many outside scientists who have devoted so much time to that Committee's work.

The re-organization is particularly striking on the research side, which for the first time in the history of the Office can now be said to be fully developed. The Director of Research, whose regrading has already been mentioned, will have under him a deputy-director especially responsible for research in physical meteorology. The assistant directorates of research, all at the senior principal scientific level and increased in number by two, will be respectively responsible for controlling research in dynamical meteorology—primarily in numerical forecasting—in synoptic meteorology, special operational investigations, climatological research, atmospheric physics, and instrument development. The post of head of the Meteorological Research Flight, one of the world's primary units of upper air research, has been raised to senior principal scientific officer.

The system of general supervision of the work of the Office by the Meteorological Committee has been changed. The Brabazon Committee reported that the previous Meteorological Committee, which was a large body representative of Government departments using the services of the Office, of the Royal Societies of London and Edinburgh, and the universities, had ceased to perform any very useful function. The Committee recommended the formation in its place of an advisory committee from outside Government service. The Secretary of State accepted this advice and has established a new Meteorological Committee consisting of an independent chairman, two scientists and two laymen. One of the scientists is to be the chairman of the Meteorological Research Committee and the other is to be appointed in consultation with the President of the Royal Society. The Committee will keep under review the progress, efficiency, broad policy and scale of effort and cost of the Office and ensure the maintenance of adequate contacts between the Office and users of its services. The chairman is Lord Hurcomb and the members are Sir Austin Anderson, Sir David Brunt, Sir Charles Normand and Colonel Stopford Sackville. The Meteorological Office Advisory Council for Scotland remains unchanged.

The Brabazon Committee welcomed the decision already taken to bring together the headquarter units of the Office, now situated in central London, Harrow and Dunstable, into a single group of new buildings at Bracknell. The benefits of the reorganization will be fully felt when the new buildings, of which the planning is now well advanced, come to be occupied.

ROTHAMSTED EXPERIMENTAL STATION

THE agricultural production of the British Isles, while high for the available area of land, is still capable of great expansion. Sociological considerations apart, increases in production will, to a great degree, depend on the work of agricultural research stations. Among these stations, Rothamsted is pre-eminent in the breadth of studies carried out. Its activities are, of course, not confined to the British Isles but are gradually reaching out to many parts of the world, and the Station regularly participates in work on agricultural problems of great importance to the Commonwealth.

It is impossible in the compass of a short article to do justice to, or to present a really fair picture of, the great variety of pure and applied studies being made at such a station. The following account merely mentions some lines of investigation which struck the writer as being of particular interest and which may stimulate the reader to study the report* itself.

In the Physics Department studies continue on the microclimate in crops of wheat and potatoes. In particular, data have been obtained on the condensation and evaporation regimes and a special recording anemometer has been developed for measuring low wind-speeds within the foliage. Further important fundamental studies have been on the surface physics of clays and the mechanism of soil structure-formation. The latter subject is reviewed in a special article at the end of the report.

The Chemistry Department reports a large and varied programme of work. Experiments on the placement of fertilizers have continued, and the effects of different nitrogenous fertilizers, including formalized casein, have been studied on a wide range of crops. Work on the loss of nitrate by denitrification has shown that such loss is insignificant if the moisture content of the soil is less than 60–70 per cent of water-holding capacity. Studies on phosphate uptake using fertilizers labelled with phosphorus-32 show that the radiation effects of the active isotope are generally negligible.

The Pedology Department, in close collaboration with the Soil Survey, has continued to investigate the nature of soil parent materials derived from both igneous and sedimentary rocks. Important information on the formation of aggregates and the location of exchangeable cations is being obtained by calorimetric methods. Among other projects, work is continuing on water-absorption and potassium fixation by clay minerals and on the nature of the leaf extracts which affect constituents of soil profiles.

The Soil Microbiology Department is mainly concerned with the biological interactions in soil which encourage or control the growth of micro-organisms. The micro-population of the rhizosphere is, of course, specially important since it may influence the availability of nutrients and may include pathogens. A group of bacteria resistant to certain antibiotics has been found to be abundant in the root surroundings but rare elsewhere in the soil. Other important studies include the decomposition of herbicides and insecticides in the soil and the processes of root-hair infection by nodule organisms.

---

*Report of the Rothamsted Experimental Station for 1956. Pp. 280. (Harpenden: Rothamsted Experimental Station, 1957.) 10s.

Investigations in the Botany Department have shown that the higher yields of improved strains of barley and beet are not due to higher net assimilation-rates or greater leaf area but to a more effective translocation of the products of photosynthesis. It appears that the efficiency of photosynthesis cannot be significantly increased by breeding. Ecological studies of weeds have cast doubt on the efficacy of temporary leys as a means of eradicating wild oats.

The emphasis of the work of the Biochemistry Department is on the nature of enzyme action. The enzyme from bracken that destroys vitamin B has been prepared in a stable form, and its action has been studied by improved methods. Studies of tobacco mosaic virus have shown that the whole virus is not essential for infectivity, but that a low level of infectivity is associated with fragments of it. Some parts of the enzymic processes by which viruses lose their infectivity on storage in the laboratory have been examined as a preliminary to studying the mechanism of attack on susceptible hosts.

Members of the Plant Pathology Department are also studying the tobacco mosaic virus and have shown that infectivity may reside in the nucleic acid fraction and antigenic specificity in the protein. Five viruses infecting leguminous plants were identified and five more in cereals and grasses. This raises the very interesting question as to whether the beneficial effects of ploughing-up and re-seeding old leys may be partly due to the elimination of virus-infected grasses and clovers. Important work continues on sugar-beet virus and, on the mycological side of the Department, on potato blight.

The Nematology Department has paid particular attention to bud and foliar nematodes. Work is continuing, in association with the Biochemistry Department, on the hatching factors given out by potato roots, and preliminary studies have been made of the factors affecting hatching of eggs from cysts of beet eelworm and on the movement and activity of larvæ in soil.

The Insecticides Department is working on the persistence and fate of insecticides in the soil. The factors influencing the toxicity of insecticides are also receiving attention. Toxicity is, for example, influenced by temperature, and the effect of change of temperature on speed of action differs for the different insecticides. Further work has been done on the mode of action of the organo-phosphorus insecticides. It is known that they affect choline esterase, and a comprehensive study of this enzyme as it occurs in insects is being made. The effect of plant protection chemicals on beneficial insects have been further investigated and techniques devised for the diagnosis of poisoning in bees.

The Entomology Department has carried out regular surveys of Rothamsted and Woburn farms for pest insects which will be of the greatest value to those carrying out experiments in these areas. Investigations have been started of the influence of climatic factors on insects: in the field on the effect of microclimate on growth, and in the laboratory on the relation between fat metabolism and temperature. Work on the wheat bulb-fly has continued, with special attention being paid to the reaction of the larvæ to plant exudates.

In the Bee Department a very important advance has been made in the study of European foul brood. *Streptococcus pluton*, an organism suspected of causing the disease, has been isolated in pure culture, and it has been found that this organism and *Bacillus eurydice* have both to be present in a larva to cause the disease. Di-*n*-decyldimethylammonium bromide promises to be an effective control. Further studies have been made of the nature of 'queen substance'. It has been found that 'queen substance' received in regurgitated food from other workers is sufficient to inhibit development of the ovaries in the absence of a queen. It has also been shown that mammalian hormones such as androsterone, as well as extracts from queen ants, inhibit ovary development.

In the Statistics Department the electronic computor is now fully occupied, and an interesting application is the analysis of some of the very long-term experiments at Rothamsted. A useful account of the computor and its capabilities is given at the end of the report. Nation-wide surveys of fertilizer practice and cattle diseases are in progress.

Progress reports are also given by the Field Experimental Section, the farms at Rothamsted and Woburn, the Soil Survey of England and Wales and the advisor in tropical soils. The report closes with the review articles on soil structure and the electronic computor referred to above. R. M. S. PERRIN

ASTRONOMY AT THE CAPE OF GOOD HOPE

THE Report of Her Majesty's Astronomer at the Cape of Good Hope to the Secretary of the Admiralty for 1956[*] appears under seven headings. In the first of these, "Buildings and Grounds", reference is made to the amount of maintenance work that has been carried out, with the result that the general condition of the buildings and grounds is now very satisfactory. A new building has been erected to house the Lyot heliograph, and the new 65-h.p. fire pump, mentioned in the report for 1955, was installed in January—fortunately in time to prevent large grass fires in February and March in adjoining properties from spreading into the Observatory grounds.

Under "Instruments", accounts are given of the work carried out with the reversible transit circle, the Victoria telescope, the astrographic telescope, the 18-in. reflector, the photoheliograph, and the new d.c. amplifier (No. 6) for the astrographic photometer, which was started in 1955. The first visual observations made with the 18-in. reflector showed that a number of minor modifications were necessary, and when the report was compiled it was hoped that the instrument would be brought into routine use during the first half of 1957. A third Brown recording potentiometer has been purchased for use with the instrument.

---

[*] Report of Her Majesty's Astronomer at the Cape of Good Hope to the Secretary of the Admiralty for the year 1956. Pp. 11. (Cape of Good Hope: The Observatory, 1957.)

"Observations and Reductions" includes the routine work with the reversible transit circle, with which a total of 11,801 transits were observed during the period under review, and 530 observations were also made of the Sun, Moon, the planets and Ceres and Vesta. Of the other nine sections of this programme, reference may be made to "Proper Motions", for the determination of which 68 plates were taken with the astrographic refractor. Owing to the poor condition of the axes of the telescope, which made precise guiding of long exposures very difficult, this programme was not stressed during 1956. After the renewal of the main bearings early in 1957 every effort will be made to complete this programme as quickly as possible. Among matters of interest in "The Radcliffe Section" special mention may be made of the work of Dr. D. S. Evans, who obtained measurable spectra of five regions, in *NGC* 253, using the Newtonian spectrograph. It was possible to identify the nearer edge of this extragalactic nebula and to trace out its spiral arm system, and the spectrograms show that the system is rotating with the arms trailing. It may also be mentioned that a start has been made with the production of an atlas of southern extragalactic nebulæ: this atlas will consist of enlarged prints from selected plates, each plate being accompanied by a short description.

One disconcerting feature is mentioned under "Personal Establishment", which may not, however, be confined in its implications to the southern hemisphere. Only one Observatory officer of those recruited since the War remains on the staff, most of the others having resigned at one time or another to take up more remunerative employment. H.M. Astronomer, Dr. R. H. Stoy, adds the following comment: "This once again emphasizes the many representations that have been made to the Admiralty that the conditions and prospects at present offered are completely unattractive to potential recruits".

Under "Miscellaneous", reference is made to the regular meetings of the Cape Centre of the Astronomical Society of South Africa, and on the second and fourth Saturday evenings of each month members of the Centre have been in attendance, when the weather is fine, to show members of the public celestial objects through the 6-in. telescope. These meetings have been well attended and greatly appreciated by the public.

LINNÆUS

THE Swedish Linnean Society this year celebrated its fortieth anniversary. There are twenty or so Linnean Societies (that of London being the oldest); but the Svenska Linné-Sällskapets differs from the rest in being concerned solely with Linnæus.

The Årsskrift for 1956–57 (Vols. 39–40. Pp. 198+24. Uppsala: Almqvist and Wiksells Boktrykeri *AB.*, 1957) is admirably produced. It is surprising how, year after year, a considerable volume is issued throwing further light on aspects of Linnæus's life, writings, associations and period, and this, of necessity, with little reference to the mass of material at Burlington House in London. (Incidentally, this material still needs a good deal of sorting by someone thoroughly competent in Swedish and Latin—and able to read Linnæus's writing—such as Dr. A. Hj. Uggla, secretary and editor of the Swedish Society, who has given such valuable service in this connexion.) The first paper in the present volume is "Linnæus and Cornwall" by Spencer Savage. Its title might lead one to think that Linnæus had contrived to visit the county during his short time in England in 1736, but it refers to his interest in Cornish mineralogy. W. Borlase, vicar of Ludgvan, well known for his "The Natural History of Cornwall", was asked by his friend, John Andrew, then studying medicine at Leyden, to send a "little box" of various ores and mundics apparently to gratify the curiosity of Boerhaave. The minerals sent were shown to Linnæus who, in the opinion of Boerhaave, "understands the nature of all kinds of mettals the best of any one in the World". Gronovius undertook their naming and sent a list following Linnæus's nomenclature. A further collection was forwarded, and, with their names, Gronovius sent a copy of a report he had received from Linnæus on the liquefaction of copper. (A third set of minerals was sent, after Linnæus had left Leyden, but no copy of this was found in Borlase's papers at Penzance and Truro.)

A. J. Boerman writes about Linnæus's candidature for his medical doctorate. To save both time and money, many Swedish medical students took their degree at the University of Harderwijk previous to hearing Boerhaave's lectures at Leyden. Before presenting and defending his thesis Linnæus had to show that his general medical knowledge was of the standing expected of a doctor. It is known that he had written his thesis before leaving Sweden; but the day after arriving at Harderwijk he had to prepare a manuscript for his Candidatus Medicinae. The text of what appears to be a fair copy of the Latin original (Linnean Society, London) is given and its English translation. There is certainly much still to be learned about Linnæus's activities in Holland.

The remaining eight principal papers are in Swedish. Carl-Axel Torin writes on Linnæus as 'rusthållare' in the horseguards. At that time landlords, as part of their tenure, had to procure and maintain a number of soldiers for the standing army, and provide them with a small plot of land. The archives of the regiment show that when Linnæus acquired Hammarby in 1758 he was responsible for four dragoons and their horses. During the Seven Years War two of these dragoons lost their lives and Linnæus had much difficulty in replacing them.

A long contribution by Gunnel Hazelius-Berg and Sigurd Wallin deals with Linnæus's wardrobe at Hammarby, with much contemporary allusion. It is amusing to find that the three-cornered hat, covered with pale green silk with a rose-coloured band, so often figured as his Dutch doctor's hat, is simply one of the kind received by the successful candidates for the medical doctorate at Upsala.

Nils Sylvén gives a catalogue of the plants of Linnæus's native parish, collating his data with those given by Linnæus, and Assar M. Lindberg, recording the tradition that three ecclesiastical families in Småland—Lindelius, Tiliander and Linnæus—took their names from a large lime tree at Jonsboda, shows that both Linnæus's father, and Tiliander, the father's uncle, so derived their names, but not Lindelius. The tree disappeared about 1823, but its site is still pointed out. Olaf Svanberg writes on "Pan Svecicus". Linnæus, in his Dalecarian journey in 1734, noticed how horses avoided certain plants. This prompted a study of which plants were eaten by various domestic animals, and twenty years later he formed a team of about thirty students to make observations; in 1749 he published a list of 600 species ("Pan Svecicus"). Prof. Svanberg has carried out an investigation on similar lines, and has established that lymphadenosis, a disease among cattle in one district of Sweden, is caused by calves eating *Ranunculus acris* which is now left standing in the fields.

Hugh Osvald discusses Linnæus's 'hay-seed'. During practically the whole of the eighteenth century Swedish agriculturists suggested the introduction of foreign plants as a means of improving fodder. Linnæus stated that a Swedish plant, *Medicago falcata*, would serve this purpose; but, in spite of his prestige, his suggestion was not generally accepted. Recently this plant has been crossed with other species of the same genus with the object of producing a fodder suitable to Swedish conditions.

A. Hj. Uggla publishes a series of letters from the younger Linnæus to Abraham Bäck, his father's most intimate friend, written in 1778, the year after his death. They contain the son's answers to questions put while Bäck was writing his commemorative address for the Academy of Science. They are of great value in throwing light on Linnæus's character and ideas and also give an impression of the difficulties the son had in following his father as professor, without his standing.

A number of smaller papers on points concerning Linnæus and the Society add to the picture of lively interest.

There is an English summary of the principal contents. A most valuable supplement is an index to the content of the forty volumes of the yearbook, which contains a wealth of information that will prove invaluable when a reasoned account of Linnæus as a scientist, his influence on the development of ideas, and his personality is attempted.

J. RAMSBOTTOM

APPLIED PROBABILITY

"APPLIED Probability" is an exceedingly valuable collection of papers badly mistitled*. In no sense could the first three contributions (by Lévy, Doob and Feller) be regarded as essays in *applied* mathematics. Thus, Lévy's paper, ostensibly about Brownian motion, studies an abstraction of that phenomenon involving $(2p + 1)$-dimensional 'time', which would not be appropriate for the description of the physicists' Brownian motion even when $p = 0$. This comment is not intended to be uncomplimentary; rather the reverse. The reviewer only regrets that many who would find interest and even inspiration in this book will leave it unopened because of its unfortunate title.

To return to Lévy's paper, a fascinating and apparently very difficult problem is suggested by the series of papers by Lévy, of which this was the first to be written (though not the first to appear). Let E_n be real n-dimensional Euclidean space (or Hilbert space, when we write $n = \infty$), and let $d(x,y)$ denote the distance between the points x and y in E_n ($\| x-y \|$, if $n = \infty$). Then it is known that a Gaussian random function $f(x)$ can be constructed in such a way that

$$\mathcal{E}\,(f(x) - f(y)) = 0\,; \quad \operatorname{var}\,(f(x) - f(y)) = d(x,y)$$

If A is a set of points in E_n, and if the values of $f(x)$ for x in A are given, then Lévy writes $\mathcal{E}\,(\ldots \mid A)$ and $\operatorname{var}\,(\ldots \mid A)$ for the corresponding conditional means and variances of various random quantities. In particular, if S_t is the surface of a sphere centred at the origin in E_n and of radius t, and if K_t is the region outside S_t, Lévy considers the quantities

$$\operatorname{var}(f(0) \mid K_t) = c_n t \text{ and } \operatorname{var}(f(0) \mid S_t) = c_n' t$$

which plainly depend on t in the manner indicated and on the dimensionality n. When n increases, c_n and c_n' both decrease, and it is asserted that

$$\lim_{n\to\infty} c_n = c_\infty = 0\,; \ \lim_{n\to\infty} c_n' = c_\infty' = 1 - 2^{-1/2}$$

Now $f(x)$, as a random variable having a finite variance, can be identified modulo a suitable equivalence with a point in the Hilbert space of random variables having a finite expected square; thus, in the case $n = \infty$, we can think of $f(.)$ as mapping one Hilbert space into another in such a way that

$$\| f(x) - f(y) \| = \sqrt{\| x-y \|}$$

The existence of such square-root mappings is well known and some of their surprising properties have been studied[1]. One of the results of Lévy which has been noted above suggests that the following geometrical relation ought to hold for square-root mappings of the kind just described: $f(0)$ lies in the closed linear variety spanned by $f(K_t)$. If this could be proved directly, much insight would be gained into the studies Lévy has made of such many-parameter 'Brownian motions'.

The papers by Doob and Feller may both be regarded as contributions to generalized potential theory. Doob's paper summarizes results which have already been reported by him in detail elsewhere[2] and which are concerned with solutions to abstract problems of the Dirichlet type directed by the following key idea: the boundary is to be approached in such a way that the instantaneous motion at any point is controlled by the harmonic measure. There is a slight link with Lévy's paper in that in some simple concrete situations the trajectories will be those of one-parameter Brownian motion. Doob's paper is again one of a long series; the latest has just appeared in the Russian probability journal *Teoriya Veroyatnostei*. Feller might be said to be writing about generalized discrete harmonic functions; specifically he studies the solutions to the equations

---

* Applied Probability. (Vol. 7 of Proceedings of Symposia in Applied Mathematics of the American Mathematical Society.) Pp. v+104. (London: McGraw-Hill Publishing Company, Ltd., 1957.) 37*s.* 6*d.*

$$x_i = \sum_{j=1}^{\infty} p_{ij} x_j \quad (i = 1,2, \ldots) \qquad (1)$$

where the coefficients p_{ij} are non-negative and sum (over the suffix j) to unity for each separate i. Such *stochastic matrices* (p_{ij}) are of immense importance in modern probability theory. The structure of the set of natural solutions to the associated equations

$$y_j = \sum_{i=1}^{\infty} y_i p_{ij} \quad (j = 1,2, \ldots)$$

(that is, the solutions such that $\Sigma \mid y_i \mid < \infty$) is relatively simple and has been known for some time, but the structure of the set of natural (in this case, bounded) solutions to (1) is exceedingly intricate and is just now being unravelled by Blackwell[3] and Feller. Feller studies among other things the extremal solutions to (1) and their relation to the various possible 'escape routes' for systems the stochastic motion of which is governed Markov-chainwise by the matrix (p_{ij}). It has been customary in the past to speak of the system's escape to 'infinity' if the (Cesàro) limits of the n-step transition probabilities do not total j-wise to unity. This use of language should imply that the set of states (1, 2, 3, . . .) has been compactified by the addition of a single 'point at infinity'. The main content of Feller's work shows how much more fruitful it is to adopt a more discriminating compactification, so that (so far as possible) distinct escape routes shall be provided with distinct destinations on the boundary. Feller's boundary is constructed in terms of maximal ideals in the lattice of non-negative solutions to (1). Vast new perspectives in the theory of Markov chains and processes are opened up by this work, which is a summary of a longer paper already published elsewhere[4].

The papers by Hopf and Batchelor at last make contact with the real world, the subject-matter of both being the statistical theory of turbulence. Hopf discusses this with the aid of the characteristic functional, a technique introduced by himself in turbulence theory and independently and in other contexts by Le Cam, Bochner and others. Batchelor's object is to point out that a mathematical model of turbulence is inadequate if it leads to a spectrum analytic near zero wave-number, the essential non-analyticity being associated with requirements imposed by the Navier–Stokes equation.

Münch writes on stochastic processes in astronomy. Consider, for example, an infinite galaxy containing a uniform distribution of emissive material and superpose on this a Poisson distribution of absorbing clouds all having the transmission factor q $(0 < q < 1)$. Then with suitable units the intensity observed in a particular direction will be

$$U = u_0 + qu_1 + q^2u_2 + q^3u_3 + \ldots \qquad (2)$$

where the u's are independent random variables having the distribution $\exp(-u)\,du$ $(0 < u < \infty)$. Write $F(V) = \text{prob } (U \leqslant V)$. One of the simpler problems discussed by Münch is the determination of $F(V)$. One simple method of procedure would be as follows: if $s > 0$ then the Laplace transform $\varphi(s)$ of the distribution of U will be

$$\varphi(s) = \mathcal{E}\{\exp(-sU)\} = \prod_{r=0}^{\infty} (1 + q^r s)^{-1}$$

$$= \sum_{m=0}^{\infty} A_m (1 + q^m s)^{-1}$$

say. Now

$$\varphi(s) = \varphi(qs)/(1 + s)$$

and on manipulating the partial fractions we easily find that

$$A_m = -q^m (1 - q^m)^{-1} A_{m-1} \quad (m = 1, 2, 3, \ldots)$$

so that

$$F(V) = C \sum_{m=0}^{\infty} (-)^m \left(\prod_{n=1}^{m} q^n/(1 - q^n) \right) (1 - \exp(-V/q^m)$$

where C is a normalizing constant. When a finite galaxy is considered, or when the transmission factor q is allowed to be a random variable, the problem is more difficult.

In the next paper Kac surveys equilibrium problems in statistical physics, and problems concerning the approach to equilibrium. In Part 1 he discusses the Ising model, the spherical model and the problem of the imperfect gas. In Part 2 he summarizes his "Foundations of Kinetic Theory" (ref. 5). There is much to interest the analyst in these apparently 'applied' papers.

Ulam's and Koopman's contributions are apparently less mathematical in content, being largely written in prose. Koopman discusses the foundations of probability theory in relation to quantum theory; Ulam reports on a number of studies he has made with John Pasta of mathematical 'models' rather different from those commonly discussed in physics but which, he thinks (and the reviewer agrees), may be found useful in the future. For example, consider the lattice of points with integer co-ordinates in n dimensions $(1 \leqslant n \leqslant 3)$, and assign to each lattice-point mass one or mass zero, with equal probability, the assignments to be made independently. Now rub out the construction lines (the lattice), think of the array of masses as lying in E_n and let them attract according to the law of the inverse square. It is stated that the resultant force can be well defined for all $t \geqslant 0$, and that the motion for all $t \geqslant 0$ can be studied if collisions are handled by assuming coalescence and conservation of mass and momentum. When $n = 1$, the author asserts that (i) the masses appearing in the course of time are unbounded, (ii) some particles will always remain single, (iii) the asymptotic density remains constant, and (iv) arbitrarily large 'holes' will appear in the system. The mathematics of the problem is vastly more difficult when $n = 2$ or 3, and here the author and his collaborator had to resort to Monte Carlo techniques. The results quoted are very instructive, and one looks forward to reading a more detailed account of this work. One is reminded of the balance between diffusion and accretion which is sometimes indicated (for example, by Jeans[6]) as a mechanism for stellar evolution. A detailed handling of this astronomical problem would undoubtedly raise questions of the kind considered here.

USE OF FARADAIC RECTIFICATION FOR THE STUDY OF RAPID ELECTRODE PROCESSES

By Dr. G. C. BARKER, R. L. FAIRCLOTH and A. W. GARDNER

Chemistry Division, Atomic Energy Research Establishment, Harwell

SEVERAL workers[1,2] have observed a small change in mean potential when an electrode is polarized by a sinusoidal alternating current. This phenomenon, which has been aptly termed faradaic rectification[2], is caused by the non-linearity of electrode processes as regards the variations of their rates with potential. Theoretical treatments have been given by Doss and Agarwal[3,4] and Oldham[2] for an electrode in contact with a solution containing a simple redox couple. The former workers considered only the case in which the concentrations and diffusion coefficients of the reactants are equal and found that the mean potential change for constant alternating component of potential approached a limiting value as the frequency increased. This limiting value was proportional to $1 - 2\alpha$, where α is the transfer coefficient of the forward process of the electrode reaction. Oldham, however, found that the potential change approached zero for all values of α as the frequency increased. Some time ago we had occasion to consider the same system. For the redox reaction

$$O + n\varepsilon \rightleftharpoons R$$

in the most general case ($C_o \neq C_r$, $D_o \neq D_r$) it was found that the potential change ψ is given by

$$\Psi_{(V \ll RT/nF)} = V^2 \frac{nF}{RT}\left[\frac{2\alpha - 1}{4} + \left(\frac{(1-\alpha)D_o^{1/2}C_o - \alpha D_r^{1/2}C_r}{2D_r^{1/2}C_r + 2D_o^{1/2}C_o}\right)\left(\frac{Zk_e + 2^{1/2}Z^2k_e^2}{2^{1/2} + 2Zk_e + 2^{1/2}Z^2k_e^2}\right)\right] \quad (1)$$

where $Z = \dfrac{D_r^{1/2}C_r + D_o^{1/2}C_o}{C_r\omega^{1/2}D_r^{1/2}D_o^{1/2}}$

In (1) C_o and C_r are the concentrations of O and R, respectively, in the bulk of the solution. D_o and D_r are the diffusion coefficients of the two reactants. V is the amplitude of the (almost) sinusoidal component of the interfacial potential and ω is the angular frequency. The rate constant at equilibrium of the forward process of the reaction (the reduction of O) is denoted by k_e.

Equation (1) applies equally well to a liquid metal electrode when R is dispersed throughout the metallic phase. It is only valid for values of V much smaller than RT/nF, and hence, in any accurate test of (1), ψ is likely to be quite small. If $C_o = C_r$ and $D_o = D_r$, (1) reduces to an equation derived earlier by Doss and Agarwal[4].

The corresponding expression for ψ in the case of an electrode reaction in which the concentration of R at the electrode surface remains constant (for example, $Hg_2^{2+} + 2\varepsilon \rightleftharpoons 2Hg$) is obtained from (1) by letting $C_o/C_r \rightarrow 0$. One then obtains

$$\Psi_{(V \ll RT/nF)} = \frac{V^2nF}{4RT}\left[2\alpha - 1 - \frac{2\alpha\,(2^{1/2}k_e^2 + k_e\omega^{1/2}D_o^{1/2})}{2^{1/2}k_e^2 + 2k_e\omega^{1/2}D_o^{1/2} + 2^{1/2}\omega D_o}\right] \quad (2)$$

For both types of reaction ψ tends towards the limiting value $(2\alpha - 1)V^2nF/4RT$ as ω increases, thus making possible a direct determination of the transfer coefficient if V is known. Further, by studying the variation of ψ with frequency, k_e can also be determined, if the diffusion coefficients which appear in the appropriate equation are known.

The validity of (1) has been tested by studying the variation with frequency of the amplitude of the low-frequency alternating current (the faradaic rectification or F–R current) which has to be supplied to a mercury-drop electrode to keep its mean potential constant, when it is polarized by an amplitude-modulated radio-frequency current. Square wave modulation (225 c./s.) has been used, and the F–R current has been measured with a 225 c./s. square wave polarograph[5] using the basic circuit shown in Fig. 1. Frequencies between 100 kc./s. and 6·4 Mc./s. have generally been used.

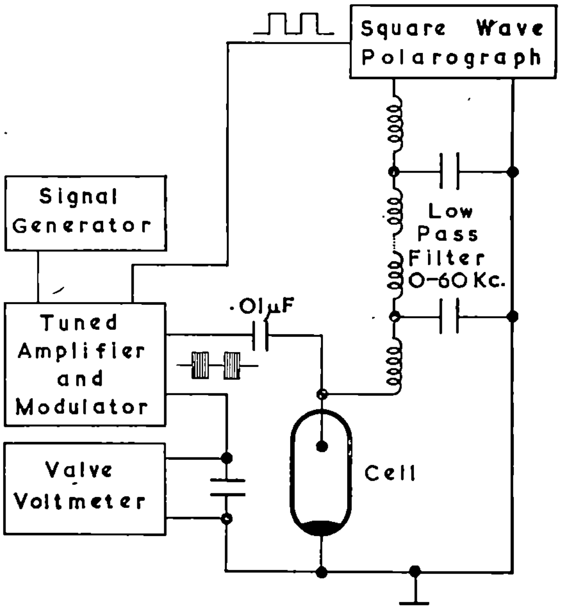

Fig. 1. Basic circuit for measurement of faradaic-rectification current

In all cases in which the kinetics have been such that the reaction at the highest frequency was almost entirely kinetically controlled, the amplitude of the F–R current for constant C_o, C_r and V has approached a limiting value, showing that ψ must also have a finite limiting value. As predicted by theory, this

value is independent of C_o and C_r and its sign is governed by the sign of $1 - 2\alpha$.

The kinetics of various rapid electrode reactions have been investigated by studying the dependence of the *F–R* current on ω and on the concentration ratio C_o/C_r, using values of C_o and C_r smaller than $\frac{2}{n^2} \times 10^{-4}$ *M* and values of *V* smaller than 5 mV. Some approximate values of α and of k_0, the rate constant of the forward process of the reaction when the rate constants of the forward and reverse processes are equal, are given in Table 1. For the reduction of cadmium ion in 0·5 *M* sulphate solution the values of α and k_0 are in fair agreement with values deduced from data given by Gerischer[6]. For the reduction of the same ion in molar potassium nitrate solution, k_0 is about ten times larger than a rate constant (approximately equal to k_0) reported by Randles and Somerton[7]. In no other cases has it been possible to compare the present results with results obtained by other workers. Table 1 shows that in some cases α is surprisingly small ($\sim 0{\cdot}07$) and in others it is unusually large ($\sim 0{\cdot}9$). In such instances the main rate-controlling step in the reduction of the ion may possibly be a chemical process. For example, slow dehydration of the ion prior to its transfer to the electrode may be responsible for values close to zero, while slow formation of a soluble intermetallic compound between the metal and mercury could lead to an apparent value of α close to unity. However, it is not easy to see why the latter process should tend to become the rate-determining process in the case of chloride solutions, and it seems more likely that the large values of α in some way are connected with the reduction of complex ions.

The faradaic rectification method appears to be a powerful method for the study of very rapid electrode processes. It is free from errors associated with the resistance of the solution such as occur when conventional methods[8] are employed. Also, if C_0 and C_r are small the interfacial impedance at radio-frequencies is controlled by the double-layer capacity, and, provided that this capacity is an aperiodic quantity, errors connected with its low impedance do not arise. To avoid systematic errors, small corrections must be applied to allow for the effect of the slight non-linearity of the double-layer capacity, and for the effect of changes with frequency in the distribution of the polarizing current over the electrode surface. At the present time, uncertainties in the magnitude of the latter correction and in the value of D_0 are often the major sources of error in the determination of α and k_0.

CONSTITUTION OF THE FIBRILLAR AND NON-FIBRILLAR COMPONENTS OF THE WALLS OF *VALONIA VENTRICOSA*

By Prof. R. D. PRESTON, F.R.S., and J. CRONSHAW

Department of Botany, University of Leeds

THE microfibrils of *Valonia* cellulose, first observed in 1948[1], have long been known to occur as flattened ribbons averaging some 200 A. in width, and perhaps half as thick[2], with the flattened faces lying more or less parallel to the wall surface. Within these microfibrils the planes of 6·1 A. spacing lie parallel to these flattened faces and therefore in turn to the surface of the wall[3]. It is now known that native celluloses in general take the same form, though the width and the thickness are usually less than those found in *Valonia* cellulose.

Various lines of evidence, however, have suggested that the microfibrils of *Valonia* cellulose type are unique in possessing an extraordinarily high degree of crystallinity. Thus the X-ray diagram of the untreated *Valonia* wall, and the electron diffraction diagram as observed in the electron microscope, suggest that the crystallites of this cellulose are about as broad as the microfibrils themselves[3,4]; the cellulose is soluble only with extreme difficulty in cuprammonium and a positive reaction with iodine and sulphuric acid or with chlorzinc iodide is always difficult to obtain and often lacking[5]; the wall does not swell in 72 per cent sulphuric acid[2] and the microfibrils are scarcely affected by acid of that strength. It has, however, always appeared to be a

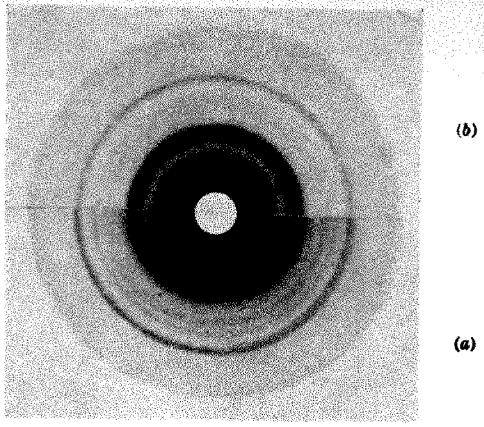

Fig. 1. X-ray powder diagrams of *Valonia* cellulose and cotton cellulose. Copper $K\alpha$ radiation collimated to a beam 0·5 mm. in diameter. Specimen-film distance, 3 cm. (*a*) a pellet of purified *Valonia* cellulose; (*b*) a pellet of purified cotton fibres

paradox that the percentage crystallinity as determined by the method of Hermans is no higher than 70 per cent[6] and therefore of the same order as that in the cellulose of many fibres in which the crystallinity is fairly low as judged by other methods.

Little is known, however, concerning the chemical constitution either of the microfibrils or of the whole wall of *Valonia*, and it is obviously essential to know something about this before the figure of 70 per cent can be made significant. During a recent investigation of the chemical constitution of celluloses from various sources[7] we have included but not reported upon *Valonia* cellulose. In this study the wall was fractionated, and the sugars in the hydrolysis products detected, by the methods of Jermyn and Isherwood[8]. In addition, the chemical extraction process described by Roelofsen and Houwink[9] was also used to obtain a preparation of the pure cellulose component. It was found that the cellulose component, observed in the electron microscope to consist entirely of microfibrils with little or no associated amorphous material, represents about 75 per cent of the wall dry weight. This therefore would seem to harmonize the results obtained by Hermans's method with the high crystallinity associated with other observations. On hydrolysis, this material yields glucose only, as shown by paper chromatography. The other wall material extracted by boiling water and by treatment with 4 *N* potassium hydroxide gave upon hydrolysis a mixture of galacturonic acid, galactose, glucose, arabinose and xylose. It is impossible to say at this time whether any of these extracted sugars were extracted from the microfibrils.

The X-ray diagram of a compacted pellet of the purified microfibrils is presented in Fig. 1*a* in comparison with a similar diagram of cotton cellulose produced under the same conditions (Fig. 1*b*). It will be clear that the prominent ring of 3·9 A. spacing (the fourth ring from the centre) is noticeably narrower than the corresponding ring in the cotton diagram. It is a little difficult to pronounce upon the relative thickness of the other rings, since the relative intensities differ, owing presumably to some trivial cause in, for example, the packing of the microfibrils. This, however, indicates without any doubt that the crystallites in *Valonia* cellulose are broader than are those in cotton, which itself is already known to be rather highly crystalline.

We suggest, therefore, that it is reasonable to consider the microfibrils of *Valonia* cellulose as very highly crystalline, consisting of a central core of crystalline cellulose measuring on an average about 200 A. × 100 A. and containing, therefore, something of the order of 600 molecular chains. These may be clothed, perhaps, in one or two layers of chain molecules the crystallinity of which is upset by the incorporation of chain compounds other than glucans; one such layer would then contain about 100 chains more randomly arranged than those of the central core.

Two further observations show that this central crystalline core does not, however, run uninterruptedly along the whole length of a microfibril, and that the microfibril is therefore heterogeneous along its length. First, treatment of the microfibrils with sulphuric acid of sufficient strength breaks down the microfibrils into shorter lengths. This supports an earlier observation[3] that when sulphuric acid begins to attack *Valonia* cellulose it does so at local regions along the microfibril. When the microfibril becomes broken through at these localities, further hydrolysis ceases. Secondly, whenever *Valonia* microfibrils are observed in an electron microscope after treatment—prolonged boiling in water is often sufficient—the effect illustrated in Fig. 2 is frequently observed. It appears that, at positions irregularly distributed along the length of a microfibril, pieces of the microfibril have been removed although the shadow produced by metal shadowing is continuous across the gap. These pieces must therefore have been removed in the electron microscope, and have presumably been so changed even by the mild treatment as to become more sensitive to bombardment by electrons. It would appear that there are regions of weakness irregularly distributed along the length of the microfibrils, in which, therefore, presumably the thickness of this central core is reduced or the crystallinity disturbed in some other way.

On the basis of the observations which indicate the presence of this solid central crystalline core, it is evident that the larger *Valonia* microfibrils are not merely aggregates of smaller microfibrils of the order of those found in, for example, wood cellulose. On the grounds of this and other evidence concerning cellulose in general, which will be published else-

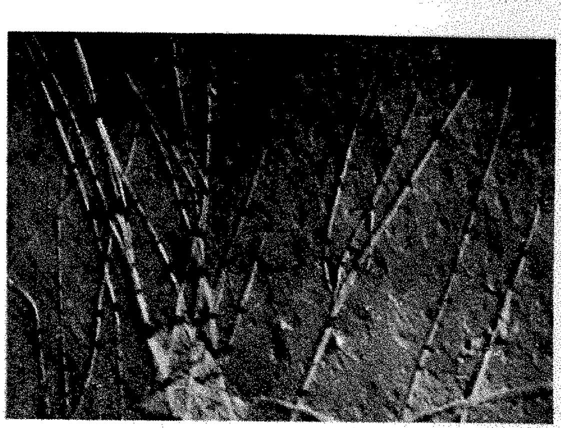

Fig. 2. Electron micrograph of *Valonia* cellulose after mild treatment with hydrochloric acid (× 24,000). Palladium–gold shadowed. Note the obvious breaks in the fibre across which the shadow is nevertheless continuous

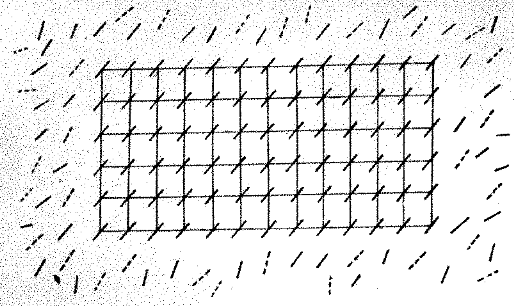

Fig. 3. Diagrammatic representation of the transverse section of a cellulose microfibril about 100 A. wide and about 50 A. thick. The solid strokes represent the planes of the glucose residues in the cellulose chain molecule and the broken strokes the planes of other sugars or sugar derivatives in non-cellulosic molecular chains. The area joined into a lattice represents the solid central core

where[10], it is suggested that the constitution of cellulose microfibrils in general is somewhat as illustrated in cross-section in Fig. 3. This figure refers to a microfibril some 100 A. wide ; an increase in the width of the microfibril would then occur chiefly by an increase in the width of the central crystalline core. This model differs from that presented by Frey-Wyssling[11] solely in the lack of 'internal' randomized molecular chains which are omitted for reasons which will be given elsewhere[10].

INHIBITION OF CAROTENOID SYNTHESIS IN PHOTOSYNTHETIC BACTERIA

Specific Inhibition of Carotenoid Synthesis in a Photosynthetic Bacterium and its Physiological Consequences

We have suggested[1-3] that the carotenoid pigments characteristically associated with the photosynthetic apparatus perform an essential physiological function, by protecting the cell from the deleterious effects of chlorophyll-catalysed photooxidations. The hypothesis was initially formulated as a result of observations on the behaviour of a carotenoidless mutant of the photosynthetic bacterium *Rhodopseudomonas spheroides*. The mutant in question synthesizes almost normal quantities of bacteriochlorophyll, but the coloured carotenoids characteristic of the wild type are completely absent from its cells, their place being taken by a much more reduced colourless C_{40} polyene, phytoene. The mutant can grow photosynthetically under anaerobic conditions in the light ; but when photosynthetically grown cells are exposed simultaneously to light and air, they are rapidly killed and their bacteriochlorophyll is destroyed. The photosensitizing pigment is bacteriochlorophyll itself. Such photosensitivity is not manifested by the wild type, or by mutants in which the normal carotenoids have been replaced by other coloured carotenoids. The correlation between carotenoid deficiency and aerobic photosensitivity has since been demonstrated by Kandler and Schötz in a mutant of *Chlorella* with derangements of normal carotenoid synthesis[4].

Specific depletion of carotenoid pigments has been caused by gene mutation in the photosynthetic organisms so far studied. We have now found that specific depletion can be produced without a change of genotype in the photosynthetic bacterium *Rhodospirillum rubrum*, as a result of growth in the presence of diphenylamine. Under these conditions, cells of *R. rubrum* become almost devoid of coloured carotenoids, but maintain a normal content of bacteriochlorophyll. Exposed to light and air, such cells display the symptoms of photosensitivity (death and chlorophyll destruction) previously observed in the carotenoidless mutant of *Rhodopseudomonas spheroides*. In *Rhodospirillum rubrum*, carotenoid depletion is readily reversible. When the diphenylamine is removed, rapid carotenoid synthesis at the expense of accumulated endogenous precursors begins immediately. The restoration of coloured carotenoids is accompanied by a rapid diminution of the induced photosensitivity. This reversible physiological induction of photosensitivity, correlated with changes in carotenoid content, provides additional experimental support for our hypothesis concerning the function of carotenoid pigments in photosynthetic organisms.

Effects of diphenylamine on growth and pigment synthesis in Rhodospirillum rubrum. The inhibition of carotenoid synthesis by diphenylamine has been observed in many fungi and bacteria, and was first demonstrated in *R. rubrum* by Goodwin and Osman[5,6]. They reported, however, that the synthesis of bacteriochlorophyll was simultaneously suppressed, an observation which we have been wholly unable to confirm. Fig. 1 shows an experiment which illustrates the strikingly specific effect of diphenylamine on carotenoid synthesis. At the point indicated by an arrow, diphenylamine (final concentration : 7×10^{-5} *M*) was added to a culture of *R. rubrum* in the course of exponential photosynthetic growth under steady-state conditions of chlorophyll and carotenoid synthesis. The synthesis of coloured carotenoids ceased immediately, whereas both growth and chlorophyll synthesis continued, though at a lower rate. The parallelism of the curves for growth and chlorophyll synthesis shows that the differential rate of chlorophyll synthesis remained essentially unchanged. The extent to which the chlorophyll :

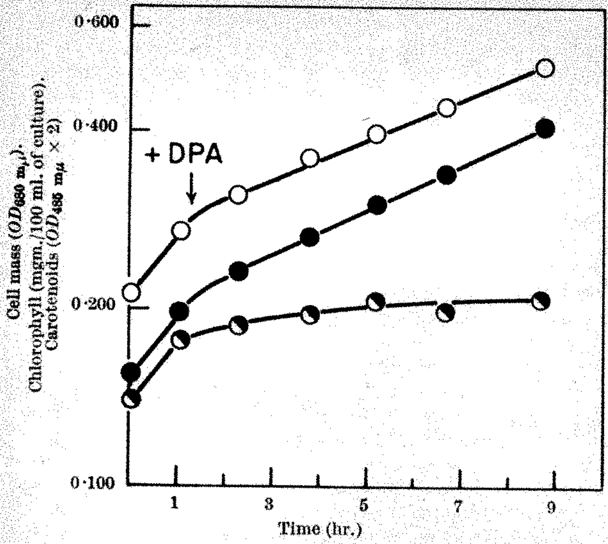

Fig. 1. Effect of diphenylamine (7×10^{-5} *M*) on growth and pigment synthesis by a culture of *Rhodospirillum rubrum*, developing exponentially in anaerobiosis and light. Pigments were measured in acetone–methanol extracts of the cells. Values for chlorophyll were calculated from the optical density of the extract at 775 mμ. Values for the coloured carotenoids are expressed in arbitrary terms, as the optical density of the extract at 485 mμ (the absorption maximum of the mixed carotenoids), corrected for light absorption at this wave-length by chlorophyll. ○—○, cell mass; ●—●, chlorophyll; ◐—◐, coloured carotenoids

carotenoid ratio can be modified by the cultivation of *R. rubrum* in the presence of diphenylamine is evident from the absorption spectra of normal and treated cells, grown photosynthetically under otherwise identical conditions (Fig. 2).

The suppression of normal carotenoid synthesis provoked by diphenylamine is accompanied by a massive intracellular accumulation of the more saturated polyenes, which are undetectable in normal cells. The major component is phytoene, accompanied by smaller quantities of phytofluene, ζ-carotene and neurosporene. Indications of this accumulation can be seen in the spectrum of the cells (Fig. 2). In treated cells, the bacteriochlorophyll peak at 375 mμ is much higher relative to the infra-red peak at 880 mμ than in normal cells. This is caused by the light-absorption of saturated polyenes in the near ultraviolet region. Quantitative analyses of the extracted polyenes, kindly performed for us by Dr. T. Nakayama, showed that the total polyene content of cells grown in the presence of diphenylamine is far higher than the content of carotenoid pigments in normal cells. In this respect as well, the findings of Goodwin and Osman[6], who detected only 'traces' of the more saturated polyenes in cells of *R. rubrum* grown with diphenylamine, could not be confirmed.

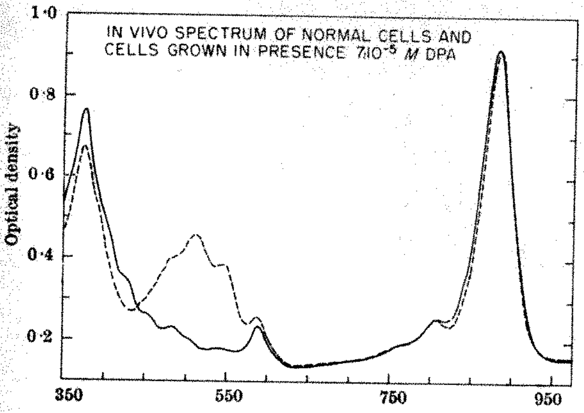

Fig. 2. The absorption spectra of two suspensions of *Rhodospirillum rubrum* grown anaerobically in the light and adjusted to the same optical density at 680 mμ before measurements were made. Spectra were determined through opal glass to reduce the effect of light-scattering. Dashed line: normal cells. Solid line, cells grown in the presence of 7×10^{-5} *M* diphenylamine

As discovered by Goodwin and Osman[6], an extensive and rapid synthesis of coloured carotenoids can occur when cells which have been grown in the presence of diphenylamine are washed and resuspended in buffer. This endogenous synthesis proceeds with equal rapidity under aerobic conditions in the dark and under anaerobic conditions in the light, but cannot occur under anaerobic conditions in the dark. It is presumably an energy-requiring process, for which energy can be supplied either by photophosphorylation in the light, or by oxidative phosphorylation in the dark. Since Goodwin and Osman could detect only traces of saturated polyenes in cells treated with diphenylamine, they assumed that the endogenous synthesis occurred at the expense of non-specific intracellular precursors. We have re-studied this question in collaboration with Mrs. Synnøve Jensen and Dr. T. Nakayama. The coloured carotenoids are in fact synthesized *exclusively* from the accumulated polyenes, through a succession of intermediates. These findings and their biochemical implications will be described elsewhere.

Induced photosensitization of Rhodospirillum rubrum. Representative results of two experiments which demonstrate the photosensitivity induced in *R. rubrum* by carotenoid depletion are given in Table 1. Cells harvested after growth in the presence of diphenylamine were washed and resuspended in chilled buffer. Aliquots of this suspension were added to aeration tubes, which were placed in a water-bath held at 30° C. and aerated with a mixture of 95 per cent nitrogen and 5 per cent carbon dioxide in the dark, to prevent any occurrence of endogenous carotenoid synthesis. At the start of experiments, the aeration mixture was changed to 95 per cent air and 5 per cent carbon dioxide. Illuminated tubes were exposed to a light intensity of approximately 1,000 foot-candles from incandescent lamps, and dark control tubes were completely shielded by a wrapping of aluminium foil. Samples were removed at intervals for determinations of viable count and chlorophyll content. As shown in Table 1, photo-killing is relatively rapid: in the presence of light and air, the viable count fell to less than 20 per cent of its original value within 2 hr. The viable counts of the dark

Table 1. PHOTO-KILLING AND CHLOROPHYLL DESTRUCTION IN BUFFERED SUSPENSIONS OF CELLS, DEPLETED OF COLOURED CAROTENOIDS BY GROWTH IN THE PRESENCE OF DIPHENYLAMINE

		Conditions of exposure		
		Air, light	Air, dark	Air, light, after 30 min. in air, dark
Exp. 1	Per cent survivors after 2 hr.	14	87·5	—
	Per cent chlorophyll after 23 hr.	39	106	
Exp. 2	Per cent survivors after 1·5 hr.	19·4	97	55·5
	Per cent chlorophyll after 23 hr.	75	100	92

controls also fell slightly, but this decline was comparatively negligible. The photo-destruction of chlorophyll is far slower than photo-killing, and much longer exposures are accordingly required for its accurate measurement. As shown in Table 1, the chlorophyll content of illuminated suspensions had declined markedly after 23 hr., whereas that of the dark controls was essentially unchanged. Comparable exposures to air and light cause no measurable death or chlorophyll destruction in normal cells.

Exp. 2 in Table 1 also illustrates the diminution of photosensitivity which occurs when cells are permitted to initiate endogenous synthesis of carotenoid pigments before exposure to light. In this experiment, an aliquot of the cell suspension was kept for 30 min. under aerobic conditions in the dark before exposure to light. The moment of light exposure was used as the zero time for measurements of viability and chlorophyll content on this tube. It can be seen that both death and chlorophyll destruction were much less rapid than in the suspension which was exposed to light and air without preceding maintenance under aerobic conditions in the dark. Desensitization was not complete; but the amount of endogenous carotenoid synthesis which had taken place at the time of light exposure was very limited. Complete restoration of the normal coloured carotenoids requires many hours.

Photo-inhibition of endogenous carotenoid synthesis. In *R. rubrum*, the photosensitivity which accompanies carotenoid depletion has one additional manifestation: inhibition of endogenous carotenoid synthesis. Fig. 3 shows the absorption spectra of acetone–methanol extracts prepared at successive intervals from two tubes of a buffered cell suspension incubated aerobically at 30° C. in the light and in the dark, respectively. Vigorous endogenous synthesis occurred in the suspension incubated in the dark, as evidenced by the increasing optical density of successive extracts in the region where light is absorbed by the carotenoid pigments. No detectable synthesis occurred in the suspension incubated in the light; in fact, the changes in the spectra of successive extracts suggest that the polyenes originally present may have been partly destroyed. A total photo-inhibition of endogenous carotenoid synthesis can be obtained only if the cells have been very thoroughly depleted of coloured carotenoids by preceding diphenylamine treatment. Once such depleted cells have initiated endogenous synthesis, the process can no longer be wholly arrested by light and air, although its rate may fall. The extent to which the rate is diminished by exposure to light and air is inversely related to the amount of synthesis which has already taken place at the time of exposure.

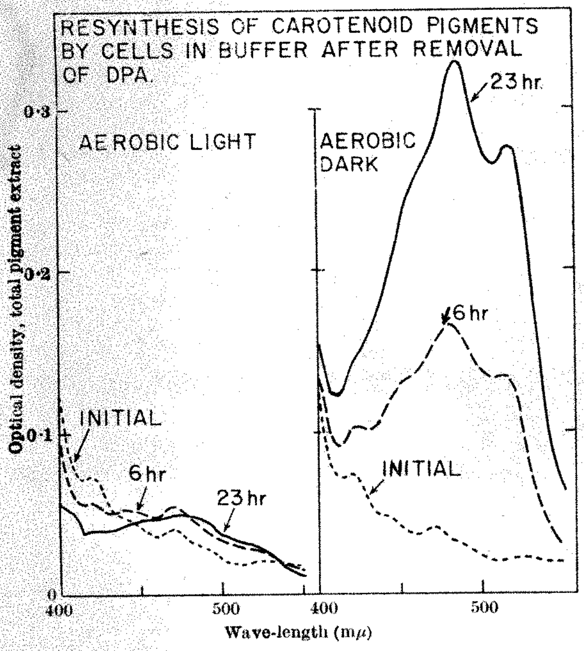

Fig. 3. The absorption spectra of acetone–methanol extracts prepared from two aliquots of a buffered suspension of cells which had been grown in the presence of diphenylamine. The suspensions were incubated aerobically at 30° C. in the light and in the dark, respectively, and samples were withdrawn after the times indicated for the preparation of extracts

The remarkable photosensitivity of endogenous carotenoid synthesis is intelligible in terms of cell structure. The normal photosynthetic pigment system of the purple bacteria is localized in macromolecular structures, variously termed 'chromatophores' or 'grana', which can be separated from other cellular components in extracts of the bacteria by differential centrifugation[7]. These bodies are the functional equivalents of plant chloroplasts, although they are much smaller and appear to be much simpler. By the fractionation of bacterial extracts, we have found that the polyenes which accumulate as a result of the diphenylamine treatment are almost exclusively associated with the chromatophores. This implies that the terminal steps of carotenoid synthesis, which take place at the expense of the saturated polyenes when diphenylamine is removed, occur in the chromatophores, where the saturated polyenes presumably fill the sites occupied by coloured carotenoids in normal cells. The substrates (and possibly also the enzymes) for endogenous carotenoid synthesis are therefore situated in the cell very close to the bacteriochlorophyll, and as a result are highly exposed to chlorophyll-catalysed photo-oxidation.

This work was supported by a grant from the National Science Foundation.

8 industrial grades
OF POROUS CERAMICS

Why not reap the fruits of our extensive research and development of Porous Ceramics for industrial uses? Whether for filtration of liquids or gases, for diffusing, aeration, flow restriction, the handling of powders, or as carriers for pastes or liquids, Porous Ceramics have provided the solution to a variety of industrial problems.

Eight grades in two different qualities are produced, ranging from 25 to 750 microns measured maximum pore size, and the material can be supplied in flat tiles, tubes, cylinders and other shapes.

Porous Ceramics have the following advantages: uniformity of pore size, pore distribution and permeability; high resistance to all acids, except hydrofluoric; cleanliness; resistance to heat and mechanical shock.

Our Research Department will be pleased to co-operate in the solution of your problems. *Write for catalogue No. 10.*

Heat for Science and Industry—11

HEAT-BY-THE-YARD

First in the field with fixed length heating tapes, Electrothermal are again in the lead with the new "HEAT-BY-THE-YARD" which can be cut to any length required, to heat any set-up, vessel, pipe or valve. Available from your usual Laboratory Supply House.

PIPE HEATERS	*—up to 100° C.*
HEATING TAPES	*—up to 450° C.*
HEAT-BY-THE-YARD	*—up to 450° C.*
THERMOCORD	*—up to 450° C.*
ARMOURED HEATERS	*—up to 800° C.*
FLEXIBLE FURNACE	*—up to 1000° C.*

phores of the photosynthetic sulphur bacterium, *Chromatium*[3]. The photochemically active particles of these obligate anaerobes produce adenosine triphosphate in the presence of light.

The function of carotenoids in photosynthesis has been an open question for many years. Evidence has been offered in some organisms for the direct participation of carotenoids in the capture and transfer of light energy[4]. Recent work has indicated that carotenoids are essential for the functioning of the 'Hill reaction' by isolated chloroplasts of higher plants[5]. Stanier[6] and co-workers have demonstrated in the non-sulphur purple photosynthetic bacteria that carotenoids protect the cell from photo-oxidations by bacteriochlorophyll. We have investigated the relationship of coloured carotenoids to photophosphorylation in *Chromatium*, by the study of suppression of carotenoid synthesis with diphenylamine.

Diphenylamine has been used for inhibiting the synthesis of coloured carotenoids in fungi, algæ and photosynthetic bacteria by Goodwin and his co-workers[7]. *Chromatium*, cultured and subcultured in the presence of diphenylamine, becomes a bright blue-green in colour and lacks any visible red carotenoids. The organisms grew readily in the presence of light with carbon dioxide as the only source of carbon, and there was no apparent effect on the total amount of bacteriochlorophyll produced. 'Carotenoidless' cells regain their coloured carotenoids in the absence of diphenylamine. Red 'Cellophane' filters were used between the light source and the cultures to reduce the destruction of diphenylamine by the shorter wave-lengths of light, and under these conditions the cells remained green during the growth period (3–4 days).

Chromatophores were isolated and concentrated as previously described[3] from both the normal and the diphenylamine-treated ('carotenoidless') bacteria, and the particles sedimenting at 144,000 *g* were washed with water before use in the following experiments. The absorption spectra of the chromatophores from both types of cells are shown in Fig. 1. As can be seen, the major coloured carotenoid peaks between 450 and 550 mμ have almost completely disappeared and there is at least one new peak at 420 mμ which probably represents a polyene precursor of the coloured carotenoids. It can be seen that the major near infra-red peak of bacteriochlorophyll is unaffected but there is a striking shift in the position of the various minor peaks. The normal chromatophores of our strain of *Chromatium* give an indication of absorption at 807, 825, 840 and 895 mμ (see Fig. 2). In the absence of coloured carotenoids (green chromatophores) the 807 peak remains unchanged and there is a peak at 830 and a shoulder at 885 mμ. Stanier shows a shift of the near infra-red peaks in his blue-green mutant of *Rhodopseudomonas spheroides* to a symmetrical band of the *R. rubrum* type. Duysens[8] has suggested that the various shapes of the multiple peaks of the bacteriochlorophyll absorption spectrum in different species may be due to a difference in the relationship of bacteriochlorophyll to various 'bearer molecules'. Stanier proposes that for his mutant of *R. spheroides* the shift is due to the substitution of the polyene precursors for the coloured carotenoids in the structural composition of the chromatophores. This hypothesis is extremely attractive for the diphenylamine-altered chromatophores of *Chromatium*, since similar shifts in the red spectrum are observed and the presence of precursors is indicated.

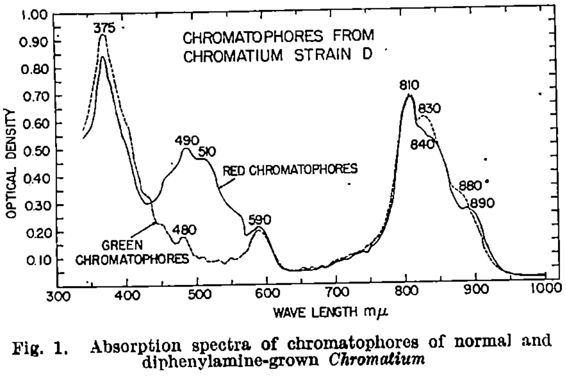

Fig. 1. Absorption spectra of chromatophores of normal and diphenylamine-grown *Chromatium*

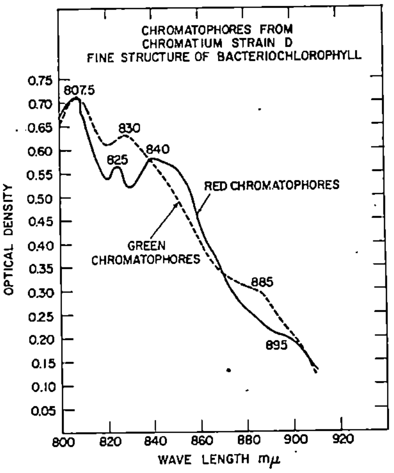

Fig. 2. Fine structure of bacteriochlorophyll absorption band for normal and diphenylamine-bleached chromatophores

Photosensitization of photophosphorylation. As previously reported, the chromatophores of *Chromatium* will make adenosine triphosphate in the presence of light and in the absence of oxygen at a rate up to 70 micromoles of phosphate esterified per mgm. bacteriochlorophyll per hour (ref. 3). Catalytic amounts

Table 1. PHOTOSENSITIVITY OF PHOTOPHOSPHORYLATION

Pre-treatment of chromatophores*		Type of chromatophore	
Illumination (min.)	Gas phase	'Carotenoid-less'	Normal
		Per cent activity†	
10 (light)	Air	0	63
10 (light)	Nitrogen	72	100
10 (darkness)	Air	100	100
30 (light)	Air	0	42
30 (light)	Nitrogen	82	88
30 (darkness)	Air	100	100
30 (darkness)	Nitrogen	100	100

* Pre-treatment of chromatophores and photophosphorylation measurements were carried out in an illuminated Warburg apparatus with 3,000 and 1,000 ft.-candles of light, respectively, at 20° C. The reaction mixtures of 3 ml. volume contained 0·1 *M* glucose, 0·02 *M* *tris* buffer at *p*H 7·8, 7·5 μmoles adenosine diphosphate at *p*H 7·8, 10 μmoles magnesium chloride, 25 μmoles orthophosphate, 0·3 ml. of supernatant from ruptured cells, 4 mgm. crude hexokinase (Sigma Chemical Co.), normal or 'carotenoidless' chromatophores containing 0·25 and 0·32 mgm. of bacteriochlorophyll, respectively. Chromous chloride was present in the centre well of the anaerobic flasks. After the various pre-treatments, the vessels were flushed with nitrogen in the dark, the vents were closed, adenosine diphosphate was tipped in, and photophosphorylation was initiated by turning on the lights. Disappearance of orthophosphate was determined (ref. 9) and used as a measure of photophosphorylation.

† Normal and 'carotenoidless' chromatophores esterified, respectively, 60 and 61 μmoles of phosphate per mgm. of bacteriochlorophyll per hour. This was used as the '100 per cent activity' figure.

of a reducing agent and a protein factor from the cellular supernatant are stimulatory but not required by the system. The effect of the absence of carotenoids on this type of system was tested as described in Table 1.

The observed diminution of coloured carotenoids has little or no effect on the ability of isolated chromatophores to carry out the light-dependent formation of adenosine triphosphate. However, activity is completely destroyed in the presence of both light and oxygen. This extends to an isolated system, the observation of Stanier that whole cells of a 'carotenoidless' mutant of *R. spheroides* are killed by light in the presence of oxygen.

According to French and Bishop[5], carotenoids are essential for the photochemical reduction of a dye by isolated chloroplasts, that is, for the 'Hill reaction'. However, coloured carotenoids do not appear to play any part in the production of high-energy phosphate by light as shown by adenosine triphosphate formation with green chromatophores. Therefore it is probable that the production of high-energy phosphate by the chromatophores precedes or is independent of the photochemically induced reduction of a dye.

This research was carried out at Brookhaven National Laboratory under the auspices of the U.S. Atomic Energy Commission.

NATURAL OCCURRENCE OF THYMINE AND THREE METHYLATED ADENINE BASES IN SEVERAL RIBONUCLEIC ACIDS

By Dr. J. W. LITTLEFIELD* and Dr. D. B. DUNN

Agricultural Research Council Virus Research Unit, Molteno Institute, Cambridge

ALTHOUGH three naturally occurring bases in addition to adenine, guanine, cytosine and thymine have been isolated from deoxyribonucleic acid[1,2], the compound studied by Cohn, Davis and Allen[3] seems the only example so far of any additional bases naturally present in ribonucleic acid. During studies on the incorporation of unnatural bases, digests of ribonucleic acid from *Bacterium coli* were found to contain in small amount a compound with spectral and chromatographic characteristics which suggested that it was the riboside of thymine (ref. 4, and Smith, J. D., personal communication). We now have considerable evidence for the natural occurrence of thymine in ribonucleic acid prepared from two strains of *B. coli* and from *Aerobacter aerogenes* and in commercial yeast ribonucleic acid. From these sources we have isolated also three methylated derivatives of adenine: 2-methyladenine, 6-methylaminopurine and 6-dimethylaminopurine. We have found the last two compounds in the ribonucleic acid of rat liver microsomes. None of these compounds appears to be that described previously, which we believe we have noted in addition in ribonucleic acid from several sources. The natural occurrence of all four bases as nucleosides or nucleotides has been described previously, since thymine and 6-methylaminopurine occur in deoxyribonucleic acid[2,5], 2-methyladenine in the vitamin B_{12}-like Factor A[6], and 6-dimethylaminopurine in puromycin[7].

The ribonucleic acid of *B. coli* has been our main source of these four bases and their derivatives. About ten grams of growing bacteria[8] was collected by centrifugation, washed with saline, and extracted overnight with 60 per cent (v/v) ethanol – water at *p*H 4 and 20°. The residue was washed twice with 60 per cent ethanol – water, and once each with 90 per cent ethanol–water, ethanol, and acetone. After drying, it was extracted with 0·1 *M* sodium citrate for 1–2 hr. at *p*H 7·2 and 100° [9]. The sediment from high-speed centrifugation was discarded and the soluble nucleic acids precipitated three times from 60 per cent ethanol – water at *p*H 4. Two nucleic acid preparations were treated in addition by the Sevag procedure[10] to remove proteins. The final precipitate was hydrolysed overnight at 30° with 1 *N* potassium hydroxide to release the ribonucleoside 2′- and 3′-phosphates. After precipitation of the deoxyribonucleic acid by the addition of two volumes of ethanol plus perchloric and/or acetic acid to *p*H 4, the digest was centrifuged and the soluble nucleotides purified by paper chromatography using *iso*propanol–water (70 : 30, v/v) with ammonia vapour[11].

Early in this work the purified nucleotides were treated with prostatic phosphomonoesterase[12], and the four compounds discovered and studied as nucleosides. In paper chromatography using *iso*propanol/water with ammonia vapour, *n*-butanol/water (86 : 14, v/v) with ammonia vapour[13], and *n*-butanol/water/formic acid (77 : 13 : 10, v/v/v)[13], each of the four nucleosides showed the same mobility as the corresponding known riboside, which we synthesized by the incubation of the known base with inosine and a nucleoside phosphorylase prepared from *B. coli*[14]. On paper electrophoresis[11] using 0·05 *M* borate buffer at *p*H 9·2, each nucleoside migrated with the known riboside ; in the presence of borate each showed a greatly reduced mobility in *n*-butanol/water/ammonia. The wave-lengths of the ultra-violet absorption maxima of these ribosides are given in Table 1. The possibility that we were dealing with deoxyribosides rather than ribosides seems unlikely, since the method of preparation of these compounds involved alkaline hydrolysis of the nucleic acid, and since they formed complexes with borate and moved with the same R_F as the synthetic ribosides in the chromatographic systems mentioned. The deoxyribosides of thymine and 6-methylaminopurine were available and showed greater mobility in the butanol solvents. Furthermore, unlike purine deoxyribosides, the purine ribosides were stable in 0·1 *N* hydrochloric acid at 20°, while they were hydrolysed in 1 *N* hydrochloric acid for 1 hr. at 100°[15]. The nucleoside of thymine was unchanged by this treatment but was hydrolysed in 72 per cent (w/w) aqueous perchloric acid in 2 hr. at 100°[16], or, unlike thymidine, by treatment with sodium periodate followed by alkali[17].

Table 1. WAVE-LENGTHS (mμ) OF ULTRA-VIOLET ABSORPTION MAXIMA OF METHYLATED BASES AND THEIR RIBOSIDES

	Base		Riboside	
	*p*H 1	*p*H 13	*p*H 1	*p*H 13
Thymine	265	291	267	267
2-Methyladenine	266	271	258	262
6-Methylaminopurine	267	273	262	266
6-Dimethylamino-purine	277	281	268	277

The four bases released by hydrolysis of the ribosides had identical ultra-violet absorption spectra (Table 1) and also identical chromatographic behaviour in four solvents to known samples of thymine, 2-methyladenine, 6-methylaminopurine or 6-dimethylaminopurine.

More recently we have isolated what we presume to be the 2′- and 3′-phosphate derivatives of the four ribosides. From the initial *iso*propanol/water/ammonia chromatogram of the soluble nucleotides we eluted the entire area between guanylic acid and the small amount of nucleosides present, and re-chromatographed this material for 48 hr. with the same solvent. By this time, two or three faint bands had separated ahead of uridylic acid ; these were eluted together and run on paper electrophoresis in 0·05 *M* ammonium formate buffer at *p*H 3·5. In this system the mobilities of the ribonucleotides of thymine, 6-methylaminopurine, 6-dimethylaminopurine and 2-methyladenine were 0·90, 0·46, 0·42 and 0·19 of that of a uridine 2′,3′-phosphate marker. Thus, thymine ribonucleotide was separated from the mixture of the nucleotides of 6-methylaminopurine and 6-dimethylaminopurine, which were then distinguished by chromatography in *iso*propanol/water/ammonia. The ribonucleotide of 2-methyladenine was sometimes present on this electrophoretic separation, but was usually found by similar electrophoresis of the uridylic acid band. In the latter instance, it could be separated from any cytidylic acid present by chromatography in *iso*propanol/water/ammonia. These four ribonucleotides were dephosphorylated by prostatic phosphomonoesterase but not by the 5′-nucleotidase present in rattlesnake venom. The ribosides so produced, as well as the bases released by subsequent acid hydrolysis, were identical to those described above.

Table 2. MOLAR PROPORTIONS OF METHYLATED BASES IN SEVERAL RIBONUCLEIC ACIDS

Source of ribonucleic acid	Moles per 100 moles of uracil			
	Thymine	2-Methyl-adenine	6-Methyl-amino-purine	6-Dimethyl-amino-purine
B. coli B/r	0·8	0·5	0·4	0·3
B. coli 15T⁻	0·9	0·25	*	*
Aerobacter aerogenes	1·0	0·25	0·25	0·1
Yeast	0·6	0·15	0·25	0·05
Liver microsomes	—	—	0·65	0·15

* Not examined

In addition to alkaline hydrolysis, we have treated the nucleic acid preparation with rattlesnake venom containing diesterase and 5′-nucleotidase, and have isolated from this digest also the ribosides of thymine (Smith, J. D., personal communication), 2-methyladenine and 6-methylaminopurine, and a small amount of material with the chromatographic behaviour of the riboside of 6-dimethylaminopurine. The preparation of the four ribosides by these two methods strongly suggests that they existed in 3′,5′-phosphodiester linkage, most likely in the polynucleotide chain. This evidence and the thorough washing of the nucleic acid preparation before hydrolysis make it improbable that we are dealing with contaminating free nucleotides. Indeed, it would be unusual for free nucleotides to exist in the 2′- or 3′-phosphate form, and we have searched for and failed to find the ribonucleotide of thymine or 2-methyladenine in the acid ethanol-soluble fraction of the bacteria.

The approximate molar proportion of each base in the five ribonucleic acids we have studied is expressed in Table 2 relative to the amount of uracil. Values were actually determined from the isolated ribosides. Whether the widespread occurrence in ribonucleic acid of small amounts of these four bases is a chance phenomenon or of metabolic importance is not yet apparent.

We are grateful to Dr. D. J. Brown, Dr. D. M. Brown and the American Cyanamid Company for gifts of chemicals, and to Dr. J. D. Smith for much helpful advice. One of us (J. W. L.) wishes to thank the Wellcome Trustees for a travel grant.

Iodine-131 in Sheep before and after a Nuclear Reactor Accident

It may be useful to compare the amount of iodine-131 in thyroids of unselected sheep slaughtered in London before and after the release of iodine from the reactor at Windscale in Cumberland on October 10, 1957 [1].

Table 1. Iodine-131 in Sheep Thyroid Glands (mμc./gm. Thyroid)

London				Munich				Nashville			
Date slaughtered (day/month)	No. of sheep	Iodine-131 in thyroids		Date slaughtered (day/month)	No. of sheep	Iodine-131 in thyroids		Date slaughtered (day/month)	No. of sheep	Iodine-131 in thyroids	
		Average	Max./min.			Average	Max./min.			Average	Max./min.
14/8	8	0·99	1·9/0·54					12/8	14	28	145/13

				8/12	6	0·10	0·2/0·05	10/12	11	0·23	0·44/0·10
20/12	26	0·14	0·19/0·12					20/12	14	0·09	0·19/0·07

* Maximum for the period September–December.

For three years our laboratory has frequently measured the iodine-131 in thyroids of sheep and cattle slaughtered in certain cities of the United States, London, Japan and Germany (Munich).

During the summer of 1957, the sheep thyroids received once each month from London contained 1–10 per cent of the amount present in thyroids from Nashville, Tennessee. This radioactivity was considered to originate west of Tennessee. Similar results were published in 1956 [2]. The reduced amount in the English and Munich animals was possibly due to the three to four additional half-lives of time necessary for the isotope to appear in the sheep of the more distant areas.

Table 1 shows that in August and September of 1957 the concentrations of iodine-131 in thyroids of sheep slaughtered in London averaged 1 mμc./gm. This was less than one-tenth of the concentrations found during the same period in specimens from Tennessee. In October the greatest concentrations in thyroids of Tennessee sheep averaged 55 mμc./gm., on October 9, the day before the Windscale incident. Most of this iodine-131 is believed to have originated from nuclear weapons tests, 1,500 miles west of Tennessee. Ten days after the Windscale release, our specimens of British and American sheep thyroids both averaged 14–15 mμc./gm.

Sheep slaughtered in Munich in early November contained 1–10 per cent as much iodine-131 as the average of Tennessee sheep. This suggests that most of the iodine-131 in the German animals could have originated west of Tennessee. The concentrations of iodine-131 in German sheep have decayed more slowly than those in Tennessee sheep. This slow decay is interesting but not unexplained.

In general, these results suggest that sheep slaughtered in London have received less iodine-131 from the Windscale incident than sheep slaughtered in Tennessee have received from distant nuclear weapons tests.

In the United States, animals grazing east of the Nevada proving ground are more sensitive indicators to iodine-131 fall-out than those west of the test site. Therefore, directly east of Windscale, sheep may have contained more iodine-131 than those reported here. It is further suggested that valuable information can be obtained by continuous monitoring of thyroids from slaughtered sheep and cattle. A good index is thus obtained regarding the biological concentration of air-borne radioactive fall-out.

This investigation was supported by grants from the U.S. Atomic Energy Commission and the U.S. Public Health Service.

Thyroid glands were sent to us by Mr. E. F. McCleary, of the Metropolitan Cattle Market, London; Herr Schurry, of Max Muhlpointner and Co., Munich, Germany; and the Neuhoff Packing Company (Division of Swift and Co.), Nashville, Tennessee.

Symmetry of Snow Crystals

The frequently portrayed beautiful six-ray star-shaped crystals of snow have long been quoted as outstanding examples of well-developed crystal forms. Despite an infinite variety in the patterns which appear, there does often exist a remarkable symmetry in the six rays, the complex tree-like pattern repeating closely in each arm, indeed, surprisingly so. Since each of the six arms of the crystal would appear to be growing independently, this symmetry poses a problem in crystal growth, for it almost seems as if each arm of the six-ray star 'knows' what the other five are doing and follows suit. In fact I believe that each arm does 'know' what the others are doing and I offer the following explanation.

I conjecture that the crystal is vibrating mechanically as a flat plate, in fact as a Chladni plate, with of course a hexagonal symmetry. Such a mechanically vibrating system will have a complex, yet fundamentally hexagonal, distribution of nodes and anti-nodes. A growing crystal is in a dynamic state, being bombarded by water-vapour molecules, some of which can and do adhere locally to promote local growth. When the molecules adhere to achieve growth at any particular region on one arm, this immediately introduces a localized damping action on the vibrations. One can certainly anticipate that in a delicate equilibrium water molecules are less likely to adhere in regions in violent motion, and more likely to adhere in nodal or damped regions. Thus once growth starts it has a tendency to continue.

But this very damping is at once felt simultaneously at the corresponding positions on the other five arms. Thus molecules arrive and adhere easily at the other five arms in precisely the same situations as on the first arm; in other words, what happens on any one arm tends to be repeated on the others; hence the symmetrical growth, despite the apparent independence of each arm. The final symmetry is then explicable purely in terms of localized damping of mechanical vibrations, provided of course that the crystal is growing in conditions of delicate equilibrium, which is doubtless the case with the very perfect examples often found.

Of course, it is possible to produce alternative explanations; but they appear far-fetched. For example, to assume that some identical dislocation factor appears throughout the whole complex pattern and therefore simultaneously influences each arm seems most unreasonable and untenable. To postulate that ambient variations (temperature concentration, etc.) could identically affect each arm at every point simultaneously seems also unrealistic.

If the conjecture as to mechanical vibration, offered here, is correct, there would appear to be several implications. Thus: (1) The freely falling snowflake, being unconstrained to vibrate, might be expected in general to be more symmetrical than one grown on a solid surface. (2) The mechanical vibration of the crystal might conceivably be detectable as an ultra-sonic sound vibration. The dimensions of typical snowflakes indicate that these would be of very high frequency indeed, would have a complex spectrum, and doubtless would have very small amplitude. Indeed the detection of any such radiation would offer a most formidable problem. (3) On the other hand, if growing vibrating snowflakes are subjected to the right kind of ultra-sonic frequency, it might well be expected that the growth symmetry would be markedly affected.

A Photographic Observation of the Satellite 1957 Beta leaving the Earth's Shadow

On December 15 a photograph of the satellite 1957 Beta was taken at the Warner and Swasey Observatory of the Case Institute of Technology, Cleveland, Ohio, which shows the satellite coming out of the Earth's shadow (Fig. 1). This observation can be used for deriving the distance of the satellite from the Earth's surface. It was concluded from visual observations made the previous morning that the satellite should leave the Earth's shadow in the constellation Ursa Major. An exposure, therefore, was started at 5h. 10m. 00s. E.S.T. with Ursa Major in the centre of the field, although the satellite was not yet visible. The satellite was first observed visually between 5h. 10m. 20s. and 5h. 10m. 30s. It is estimated that it came out of the shadow not earlier than 5h. 10m. 10s. The position where the track is first recorded on the photograph is α = 11h. 53m., δ = + 54·8°. It is possible that the satellite at this position had already left the shadow, but was not recorded earlier because it was at minimum brightness. Nevertheless, since the period of light variation was about 40 sec., the real position should be between the value already given and α = 11h. 37m., δ = + 61°. From these two positions, heights above the surface of 770 and 800 km. respectively were derived, assuming a spherical Earth and a cylindrical shadow with a radius equal to that of the Earth. If refraction is taken into account, smaller values of the height result. Assuming a deflexion of the light rays from the Sun of 1°, the corresponding heights are 713 and 739 km. It would appear then that the derived value of 785 ± 15 km. is a maximum one. From predictions of the Smithsonian Institution a height of about 1,000 km. was expected. According to our observations this is too large by at least 200 km.

Fig. 1. Photograph of the satellite 1957 Beta coming out of the Earth's shadow near γ Ursae Majoris on December 15. Exposure time: 5h. 10m. 00s. to 5h. 10m. 58s. E.S.T. (35-mm. camera, $f/2\cdot8$; Kodak 'Tri-X' film)

From observations on December 14 and 15 a period of 101·7 min. and, therefore, a value of 7,310 km. for the semi-major axis have been derived. Assuming the distance at perigee of 6,543 km. computed from the elements given in Harvard Announcement Card 1384 has not changed, the computed value of the eccentricity is $e = 0\cdot0927$. With these values the true anomaly can be derived for a given height. With the value of the inclination (62·5°) also given in Harvard Announcement Card 1384, the argument of perigee can be derived. While a height of 1,000 km. gives for the true anomaly and argument of perigee 109° and 22·5°, respectively, the corresponding values of 90·5° and 41° follow from these observations. The argument of perigee at November 4·0 was 44° according to Harvard Announcement Card 1384. It follows that the value of regression of the perigee is only −0·07°/day according to our observations, whereas a height of 1,000 km. gives a rate of −0·52°/day, close to the value of −0·6°/day given in Harvard Announcement Card 1384.

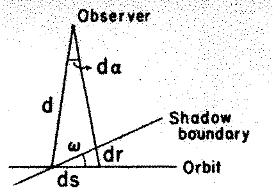

Fig. 2. The error in height as computed from the error in position. $ds \approx (2\pi d/360)\ d\alpha$; $dr \approx \tan\omega\ ds$. With $\omega_{\text{max.}} = 27{\cdot}3°$ and $d = 800$ km., $dr/d\alpha = 7{\cdot}2$ km./deg.

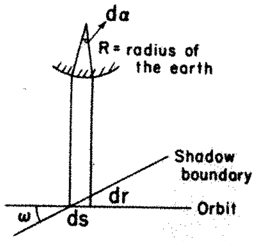

Fig. 3. The error in height as computed from the error in time. In the time dt (in min.) a point on the Earth's surface at latitude φ has moved by the amount $ds = 2\pi/360\ R \cos\varphi\ d\alpha = 2\pi/360\ R \cos\varphi\ dt/4$. $dr = \tan\omega\ ds$. $dr/dt = 10{\cdot}8$ km./min. for the latitude of Cleveland

Observations of a shadow-egress give very accurate values for the height of a satellite above the Earth's surface. At a height of 800 km. the largest angle possible between the orbit and the boundary of the shadow is 27·3°. From Figs. 2 and 3 it follows that an error in the observed position of egress of one degree results in a maximum error of 7·2 km. in the distance. An error of one minute in time results in an error of 10·8 km. in distance. Therefore, even approximate observations give rather accurate values for the height of a satellite, at least within ± 30 km. The height of 1,000 km. which was expected would require that the satellite had already left the shadow at a distance of 30° from our first observed position. There seems to be no reason why the satellite should not have been visible if this were correct.

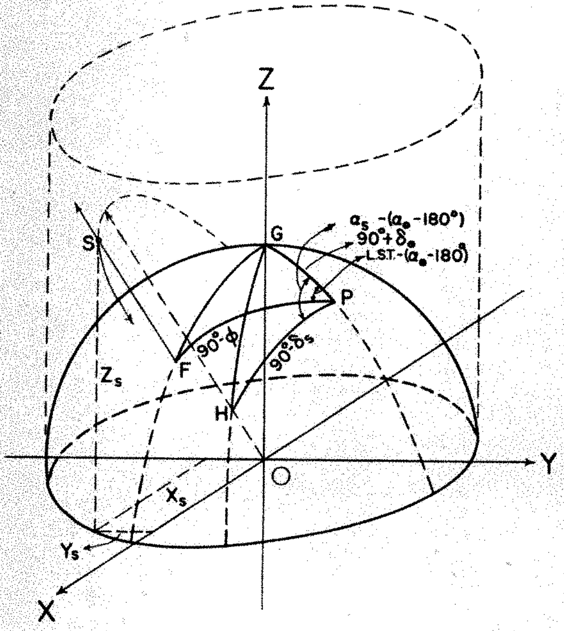

Fig. 4. Derivation of the height of a satellite above the Earth's surface. *F*, observer; *P*, pole of the Earth; *G*, point opposite to the Sun; *H*, point with the observed egress position in the zenith; *S*, satellite leaving the shadow; φ, observer's latitude; α_s, δ_s, right ascension and declination of the observed position of *S*; $\alpha\odot$, $\delta\odot$, right ascension and declination of the Sun; L.S.T., local sidereal time

The method used for the derivation is shown in Fig. 4. From the observed position of egress, the sidereal time, the latitude of the observer, and the spherical co-ordinates of the Sun, rectangular co-ordinates can be derived for the points *F* and *H*. The equations for the line $\overline{OH}$ give the direction toward the observed position of egress. The intersection of a line through *F* parallel to $\overline{OH}$ with the cylindrical or conical shadow gives the rectangular co-ordinates X_s, Y_s, Z_s for the satellite leaving the shadow. The distance from the Earth's centre is then $r = (X_s^2 + Y_s^2 + Z_s^2)^{1/2}$.

Precision Determination of the Velocity of Electromagnetic Waves

The free-space phase velocity of electromagnetic waves *in vacuo* has been measured by means of a millimetre-wave interferometer operating at a frequency of 72 Gc./s., corresponding to a wave-length of about 4 mm. The result is:

$$c_0 = 299\,792{\cdot}50 \pm 0{\cdot}10 \text{ km./s.}$$

The variation represents the standard deviation of a single observation in statistical combination with estimated systematic uncertainties, the greatest of these being in the measurement of the standards of length used (derived by optical interferometry), and in the measurement of the refractive index of the air surrounding the microwave interferometer (obtained by means of a microwave refractometer).

The 24-Gc./s. prototype instrument has already been described[1], the 72-Gc./s. interferometer being basically identical, but considerably improved in performance. A full report of the present determination will be published in due course, but it should be noted here that the value previously assigned to the one-metre length-standard used with the prototype interferometer was too great, and this has caused the published value of c_0 obtained from that instrument to be high by 0·2 km./s. Thus the corrected value of the earlier determination[1] is: $c_0 = 299\,792{\cdot}7_5 \pm 0{\cdot}3$ km./s.

This work has been carried out as part of the research programme of the National Physical Laboratory and is published by permission of the Director of the Laboratory.

Metallographic Studies of Iron Carbide and Tungsten Carbide

In most metallographic investigations of steels or of cemented carbides the fine details of the carbides are not studied. We have just completed an etching study of iron carbides made in three different ways and of some tungsten carbide (1/32-in. equilateral triangles) single crystals. The iron carbide studies, made with Carapella's reagent (5 gm. ferric chloride,

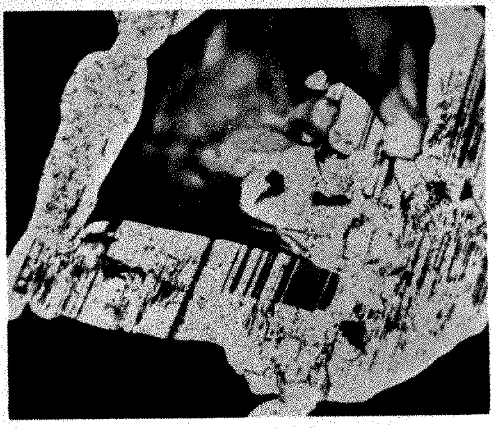

Fig. 1. Striæ in carburized iron ('Puron') carbide. Carapella's reagent. (× 1,000)

2 ml. concentrated hydrochloric acid and 99 ml. methyl alcohol) etching for 20–60 min., revealed cracking as the principal deformation mechanism and twinning as the secondary agency. The cracking behaviour has been described previously, but the twinning appears to be a new observation[1]. In two cases only, out of hundreds of samples studied, the cracks found were aligned along the twinning planes in the carbides. These observations were made upon a carburized plain carbon steel, upon a carburized 'Westinghouse Puron' iron (spectrographically pure) and upon a pure, massive, polycrystalline, iron-manganese carbide kindly supplied by Dr. L. S. Darken of U.S. Steel Research from his recent ternary system studies. In the two carburized samples there was no possibility of mechanical work having caused cracking of the carbide. Fused caustic, 50 per cent nitric acid and 50 per cent hydrochloric acid were also successful etching reagents.

The tungsten carbide crystals etched nicely in fused sodium hydroxide held just above its melting point in a nickel crucible heated electrically by a knife-blade type heater insulated with glass wool and controlled by a 'Variac'. This reagent and technique also etched pure tantalum carbide crystals. Only the fused caustic served as an etching reagent for the tungsten carbide crystals. After this caustic etching, the sample surfaces were cleaned in an acid solution, either 'Nital' or Carapella's reagent being satisfactory. For those who are concerned with hard carbides, cemented carbides, or the production of carbide die patterns, this fused caustic etching technique may prove useful.

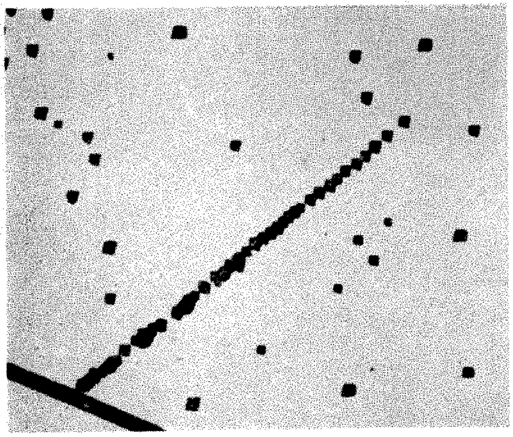

Fig. 2. Etch-pit array (dislocation line?) in iron–manganese carbide. Dark solid line in lower left is a grain boundary. Carapella's reagent. (× 625)

We believe that the twins in the iron carbides are an index of the carbide orientation and morphology. Most of the large iron carbides present in the steels are single crystals of irregular shape. The cracking and the presence of twins indicate high internal stresses.

Two Borides with the Cementite Structure

An investigation by X-ray powder methods of the nickel–boron and the cobalt–boron systems has revealed the existence of two isomorphous borides, Ni_3B and Co_3B. A nickel boride with a boron content about 25 atom per cent has previously been reported by Andersson and Kiessling[1], but no reports on Co_3B seem to have been published.

Alloys were prepared by heating mixtures of amorphous boron (99·1 per cent) with nickel powder (99·8 per cent) or cobalt powder (99·2 per cent, containing 0·45 per cent nickel) in an argon-arc furnace or in evacuated and sealed silica tubes. X-ray diffraction patterns were recorded in chromium K_a and copper K_a radiation with Guinier-type focusing cameras.

The orthorhombic unit cell of Ni_3B has the dimensions $a = 4 \cdot 389$ A.; $b = 5 \cdot 211$ A.; $c = 6 \cdot 619$ A. The lattice dimensions of this phase showed no significant variations in alloys of different composition. The unit cell of Co_3B was found to vary between $a = 4 \cdot 408$ A.; $b = 5 \cdot 223$ A.; $c = 6 \cdot 629$ A. and $a = 4 \cdot 411$ A.; $b = 5 \cdot 235$ A.; $c = 6 \cdot 634$ A. The lattice parameter values are probably accurate to 0·05 per cent. As seen from Table 1, the visually estimated intensities of the lines are in qualitative agreement with the powder data for cementite (Fe_3C) given by Lipson and Petch[2].

It is interesting to note that up to 80 per cent of the carbon in Fe_3C can be substituted by boron while retaining the cementite structure[3]. No binary boride Fe_3B seems to exist, but it may be mentioned that in the ternary system iron/boron/phosphorus a phase

$Fe_3B_xP_{1-x}$ with variable composition ($0{\cdot}5 < x < 1$) has been found which exists with phosphorus content less than 1 atom per cent (unpublished work). The structure of this phase, based on a primitive tetragonal lattice, shows no obvious resemblance to the cementite structure, however.

A detailed report of this work, together with a structure determination of Ni_3B from single-crystal data, will soon be published in *Acta Chemica Scandinavica*.

This work has been supported by a scholarship from Statens Tekniska Forskningsråd, which is gratefully acknowledged.

Amplitude of a Quartz Plate vibrating in Liquids

Some attempts have been made to measure the amplitude of a vibrating quartz crystal, but no method at present exists by which its absolute value in a liquid can be determined experimentally, although the amplitude can be calculated theoretically from the relation given by Vigoureux[1]:

$$a = \frac{2c_{11}Vd}{\pi c_1 \rho_c}$$

where c_{11} is the elastic modulus governing the thickness vibration of X-cut plate; d the change in thickness of the plate per volt (2μμm.); V the voltage applied; c_1 the velocity of sound in quartz and ρ_c the radiation resistance of the transmission medium.

The development of a thermosonic method in this laboratory has now enabled us to determine the amplitude of vibration. The principle of the method lies in evaluating the amplitude of the plane sound-wave at the source of the ultrasonic beam from the mean power of the sound from the formula[2]

$$P = 2\pi^2 \rho_c \xi^2 N^2 S$$

where N is the frequency; ξ the amplitude and S the area of source of sound. The mean power of the sound, P, is obtained from the relation[3]: $I = JH$, which involves the measurement of heat produced by a calorimetric method.

The amplitude of a quartz plate as determined from Vigoureux's formula and the amplitude of sound calculated from power measurements of the output of sound, carried out in this laboratory[4] for 1 V. input at about 5 Mc. are given in Table 1.

Table 1

Liquid	c (m./sec.)	ρ (gm./sec.^{3})	$\rho_c \times 10^{-3}$	Voltage	Ultrasonic output (watts)	$\xi \times 10^9$ (cm.)	$a \times 10^9$ (cm.)
Methyl alcohol	1,123	0·792	88·9	160	2·393	1·96	2·18
Acetone	1,192	0·792	94	158	1·626	1·59	2·06
Methyl ethyl ketone	1,207	0·805	97·2	94·5	0·579	1·56	1·99
Butyl alcohol (*n*)	1,268	0·810	103	165	1·514	1·40	1·88
Xylene (*m*)	1,340	0·863	116	158	1·364	1·31	1·67
Benzene	1,326	0·878	116	155	1·199	1·25	1·67
Chlorobenzene	1,291	1·107	143	162	1·308	1·13	1·36
Carbon tetrachloride	938	1·595	150	173	1·361	1·05	1·29
Glycerine	1,923	1·261	242	173	1·026	0·72	0·80

These results show that the agreement between the amplitudes of oscillation of the quartz and of sound is good. It is observed that the amplitude of the sound wave is always less than that of the quartz, the variation lying between 10 and 25 per cent. It is also noticed that the difference between the two amplitudes, albeit small, varies with the nature of the liquid used. It is likely that this variation is related to some property of the liquid or of the quartz crystal, although it may be due to experimental limitations.

Further investigations are in progress, and full details will be published elsewhere.

Surface Hardness of Explosive Materials by Micro-indentation

The influence of adulterating grit on the impact and friction sensitivity of a number of explosives has been shown to be considerable[1]. It is generally agreed that grit sensitizers act through modification of conditions necessary to produce frictional hot-spots, and that this process is influenced to a large extent by the hardness of the grits. Although detailed hardness data are now available for many of the common grits[2], little or none exists for the explosives themselves.

The following technique, designed to follow the modifying effect of X-rays and light on the hardness of α-lead azide, makes such detailed information readily available in many instances. The apparatus used is the Cooke, Troughton and Simms micro-indentation hardness tester fitted to a Vickers projection microscope[3]. With this instrument, materials may be indented at known load with a diamond pyramidal indenter and the indentation measured. The Vickers hardness number is obtained from the ratio of load to indentation surface.

The crystals to be tested are readily mounted in suitable presentation by the following technique. A 'Perspex' plug, ½ in. deep and machined from a rod 1 in. in diameter, is softened on one face by a few minutes immersion in chloroform. This face is allowed to become tacky in a current of warm air and is then pressed squarely down on to the crystal sample carried on a glass plate. The plug is withdrawn

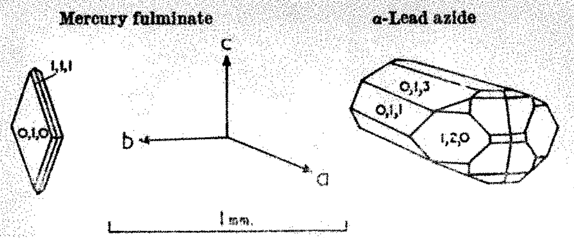

Fig. 1

and the crystals allowed to set hard. In this way, principal faces are oriented away from the plug and suitable for indentation. Lesser faces may be brought into orientation while the 'Perspex' is still plastic by careful probing under a microscope.

The plug is now inserted in the chuck of the micro-indenter and indented in standard fashion.

Small fragments of annealed 'from the melt' crystals of sodium chloride and lithium fluoride were selected as controls and mounted and indented by the above method. These two salts have hardness values of an order similar to those of the initiators mercury fulminate and α-lead azide. Vickers hardness numbers of the 1,0,0 forms of sodium chloride and lithium fluoride for an indentation diagonal of 30μ were found to be 19·5 and 103 respectively in good agreement with published values[4]. No surface hardening was observed, the apparent Meyer coefficients being widely constant over the loading range at 2·04 and 2·13 respectively.

Crystals of the two important initiators, mercury fulminate and α-lead azide, were selected for examination. Crystals of the pure material, larger than normal, were grown by crystallization from solution in aqueous ammonium chloride and ammonium acetate respectively. The faces examined were those principally defined in material used for Service purposes, and were distributed as shown in Fig. 1.

A number of crystals of each initiator were mounted and indented at various loads, results from several crystals and by two operators being incorporated in the results. The result for a 10-gm. load on the 0,1,3 form of α-lead azide is a particularly well-established value, being the result of seventy-five determinations. Figs. 2 and 3 show the plot of the logarithms of load against indentation diameter for the appropriate crystal forms.

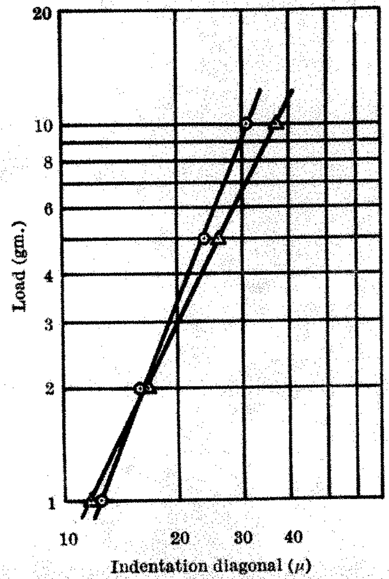

Fig. 2. A log/log plot of indentation diagonal against appropriate load for mercury fulminate: ⊙, for 1,1,1 form; △, for 0,1,0 form

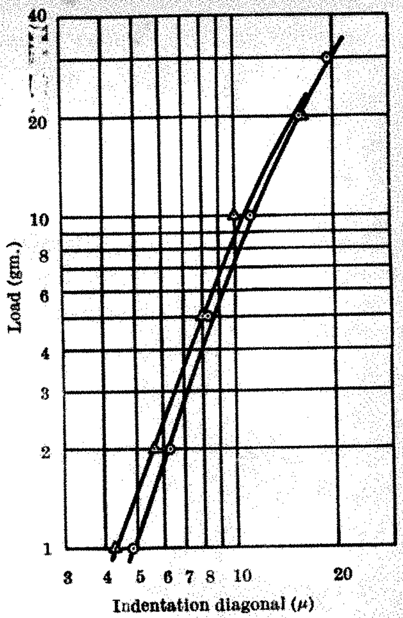

Fig. 3. A log/log plot of indentation diagonal against appropriate load for α-lead azide. ⊙, for 0,1,1/0,1,3 forms (individual curves irresolvable); △, for 1,2,0 form

Where the gradient of this line is uniform and equal to 2, the Vickers hardness number is constant for all loads: otherwise, it is variable and must be quoted against experimental conditions. In the present context, it is convenient to present the hardness figures against standard load and this has been done in Table 1.

Table 1

Initiator	Miller indices of crystal form	Vickers hardness number			
		At 1-gm. load	At 5-gm. load	At 10-gm. load	At 20-gm. load
Mercury fulminate	0,1,0 1,1,1	13·5 12·3	14·1 17·4	14·4 19·9	— —
α-Lead azide	0,1,1 } 0,1,3 }	80	131	144	145
	1,20,	99	151	165	161

These hardness values relate to material substantially unexposed to light. We have shown (unpublished work) that the hardness of α-lead azide is severely modified by exposure to soft X-rays, and related questions such as the effect of exposure to ultra-violet light are being investigated.

Vapour Pressure of Tritiated Water

A SURVEY of the literature for the vapour pressure of hydrogen tritium oxide (HTO) revealed one reference only[1]. No values were quoted for the vapour pressure at any temperature, but the authors stated the boiling point of tritiated water was less than that of ordinary water. The work reported here is the determination of the vapour pressure of hydrogen tritium oxide in the range 25–80° C.

Table 1. VAPOUR PRESSURE OF ORDINARY AND TRITIATED WATER IN MM. OF MERCURY

Temperature (° C.)	$\frac{\text{V.p. HTO}}{\text{V.p. } H_2O}$	V.p. H_2O (ref. 3)	V.p. HTO
25·70	0·77	24·76	19·07
27·84	0·81	28·05	22·72
39·98	0·84	55·27	46·43
55·02	0·88 (5)	118·04	104·47
75·60	0·89 (5)	296·3	265·2

A standard sample of tritiated water was obtained from the Atomic Energy Research Establishment, Harwell. Stock solutions of activity 4·84, 9·61, 16·75 and 24·9 μc./ml. were prepared from this standard using 'Analar'-grade distilled water. These samples were allowed to equilibriate with their vapours in a glass apparatus totally enclosed in a thermostated bath. Using this apparatus, it was not found possible to make measurements above 80° C. due to 'streaking' occurring in the high-vacuum grease used to lubricate the glass stopcocks and joints. The water vapour was isolated from the liquid phase and analysed by the butane method of Glascock[2]. At any one temperature the ratio of the activity in the vapour to that in the liquid was constant, showing that the system obeyed Henry's law. It may be shown that this ratio equals the ratio of the saturation vapour pressure of tritiated to that of ordinary water. The results are given in Table 1.

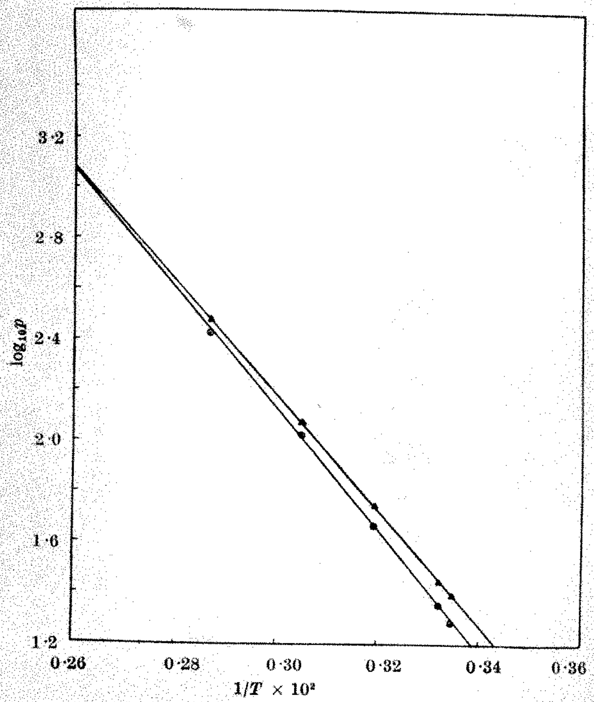

Fig. 1. Variation of $\log_{10}p$ with $1/T$ for tritiated water, ⊙ ; and for ordinary water, △

It is seen that the vapour pressure of tritiated water is less than that of ordinary water up to 80° C., and extrapolation using a $\log_{10}p$ versus $1/T$ plot (Fig. 1) shows the boiling point of the former to be greater than that of the latter. The molar heat of vaporization of tritiated water is found to be 10·9 kcal., compared to a mean value of 10·3 kcal. for ordinary water.

Use of Gaussian Functions for Intermolecular Potentials

THE purpose of this communication is to point out that the superposition of two Gaussian functions,

$$\varphi(r)^G = -C_1 \exp(-c_1 r^2) + C_2 \exp(-c_2 r^2) \quad (1)$$

with suitably chosen constants (C_1, c_1, C_2, $c_2 > 0$) provides a good approximation to the Lennard-Jones potential,

$$\varphi(r)^{L\text{-}J} = -a\,r^{-6} + b\,r^{-12} \quad (2)$$

which is approximately valid for the interaction between spherically symmetrical molecules ; and that the use of (1) leads to comparatively simple expressions in certain types of theoretical work.

Fig. 1 shows that the agreement between (1) and (2) is close except at large values of r where $|\varphi(r)|$ has become small ; the fact that (1) remains finite as $r \rightarrow 0$ does not prevent a sufficiently rapid increase with decreasing r in the practically important range. The question whether the larger number of adjustable constants in (1) offers any advantage in the direct correlation of experimental data has not been investigated.

A mathematical advantage of (1) arises from the fact that the average potential energy, $\overline{\Phi}$, of an assembly of particles interacting according to (1), and for which the probability density in configuration space is expressible in terms of Gaussian functions and their derivatives, can be evaluated in closed form. Probability densities of this type may be reasonably realistic models for the liquid (and solid) state.

In particular, (1) has been used to calculate the average potential energy for the following statistical models :

(*a*) A lattice distorted by plane displacement waves with normally distributed amplitudes :

$$\rho(\,.\,.\,\mathbf{x}_j,\,.\,.\,) = \prod_{j=1}^{j=n} \delta[\mathbf{x}_j - \mathbf{s}_j - \sum_{\mathbf{k},\alpha} \mathbf{a}(\mathbf{k},\alpha)\exp(2\pi i\mathbf{k}.\mathbf{s}_j)]$$
$$\prod_{\mathbf{k},\alpha}[2\pi\sigma^2(\mathbf{k},\alpha)]^{-1/2}\exp\{-|\mathbf{a}(\mathbf{k},\alpha)|^2/2\sigma^2(\mathbf{k},\alpha)\} \quad (3)$$

($\mathbf{x}_j$ denotes the position vector of the particle displaced from the lattice site $\mathbf{s}_j$; δ the Kronecker symbol ; $\mathbf{a}(\mathbf{k},\alpha)$ the amplitude and direction of displacement caused by the wave with the wave vector $\mathbf{k}$ and polarization α ; $\sigma(\mathbf{k},\alpha)$ are constants). One obtains for the mean potential energy between two particles attached to the lattice sites $\mathbf{s}_j$ and $\mathbf{s}_{j'}$ an expression of the form :

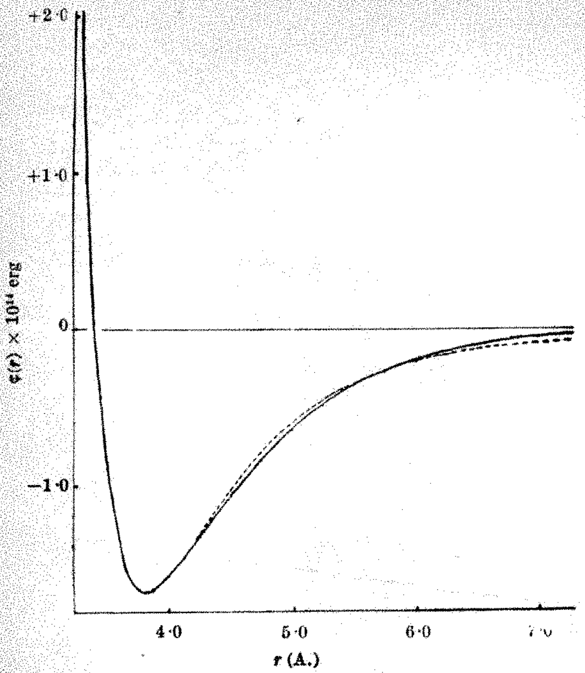

Fig. 1. Comparison of $\varphi(r)^{G}$ and $\varphi(r)^{L-J}$ for argon: – – –, $\varphi^{L-J} = -1{\cdot}05 \times 10^{-10}\ r^{-6} + 1{\cdot}63 \times 10^{-7}\ r^{-12}$ (see ref. 1); ———, $\varphi^{G} = -9{\cdot}12 \times 10^{-14} \times \exp(-0{\cdot}106\ r^{2}) + 2{\cdot}40 \times 10^{-10} \times \exp(-0{\cdot}783\ r^{2})$. φ in ergs in each case, r in Ångström units

$$\overline{\Phi}_{jj'} = -C_1\, g(c_1)^{-3/2} \times \exp\{-|\mathbf{s}_j - \mathbf{s}_{j'}|^2 f(c_1)/g(c_1)\} + C_2\, g(c_2)^{-3/2} \times \exp\{-|\mathbf{s}_j - \mathbf{s}_{j'}|^2 f(c_2)/g(c_2)\} \quad (4)$$

where f and g are polynomials of second and third degree respectively in the $\sigma^2(\mathbf{k},\alpha)$'s and in c_1 or c_2. The coefficients in these polynomials are determined by the lattice-type and by the lattice vector $(\mathbf{s}_j - \mathbf{s}_{j'})$.

(*b*) A lattice in which the displacements of particles are mutually correlated and normally distributed:

$$\rho(\,.\,,\mathbf{x}_j,\,.\,) = (2\pi)^{-3n/2}\|Q\|^{-1/2} \exp\{-1/2\sum_{j}\sum_{j'}\sum_{\alpha}\sum_{\alpha'}(x_j^{\alpha} - s_j^{\alpha})Q_{jj'}^{\alpha\alpha'}(x_{j'}^{\alpha'} - s_{j'}^{\alpha'})\} \quad (5)$$

where x_j^{α}, s_j^{α} are the α-components of the vectors $\mathbf{x}_j, \mathbf{s}_j$; $Q_{jj'}^{\alpha\alpha'}$ are (constant) elements of a symmetrical matrix which depends on the symmetry of the lattice; $\|Q\|$ is the corresponding determinant. This leads to

$$\overline{\Phi}_{jj'} = -C_1\{h_1(c_1).h_2(c_1).h_3(c_1)\}^{-1/2} \exp\{-|\mathbf{s}_j - \mathbf{s}_{j'}|^2.c_1/h_1(c_1)\} + C_2\{h_1(c_2).h_2(c_2).h_3(c_2)\}^{-1/2} \exp\{-|\mathbf{s}_j - \mathbf{s}_{j'}|^2 c_2/h_1(c_2)\} \quad (6)$$

where h_1, h_2, h_3 are linearly related to c_1 or c_2 and to the reciprocals of linear combinations of the $Q_{jj'}^{\alpha\alpha'}$.

(*c*) A probability density in which the particles are not attached to lattice sites, and which tends to zero when any two particles are too close to each other or too far apart:

$$\rho(\,.\,,\mathbf{x}_j,\,.\,) = \text{const.} \prod_{j=1,\, j'>j}^{j=n,\, j'=n} |\mathbf{x}_j - \mathbf{x}_{j'}|^{2m} \exp\{-\beta|\mathbf{x}_j - \mathbf{x}_{j'}|^2\} \quad (7)$$

where m is an integer >0, and β a constant > 0. This leads to:

$$\overline{\Phi} = \frac{n(n-1)}{2} \left| \left[\prod_{j'>j}^{n,n} \frac{\partial^m}{\partial\beta_{jj'}{}^m}\left(-H_1 + H_2\right)\right] \cdot \left[\prod_{j'>j}^{n,n} \frac{\partial^m}{\partial\beta_{jj'}{}^m}\, D^{-3/2)}\right]^{-1} \right|_{\beta_{jj'} = \ldots = \beta} \quad (8)$$

where $H_1 = C_1(D + 2c_1\partial D/\partial\beta_{12})^{-3/2}$

$H_2 = C_2(D + 2c_2\partial D/\partial\beta_{12})^{-3/2}$ and

D is the discriminant of $\sum\sum_{j'>j}^{n,n} \beta_{jj'}(u_j - u_{j'})^2$

The distributions (3), (5) and (7) are of interest as models for the liquid or solid state because they also lead to simple or manageable expressions for the configurational entropy, $S_c = -k\int..\int\rho \ln \rho.d\mathbf{x}_1..d\mathbf{x}_n$ and hence to expressions for the free energy which can be minimized (numerically) with respect to the parameters which determine the probability density (that is to say, the $\sigma(\mathbf{k},\alpha)$'s, the $Q_{jj'}^{\alpha\alpha'}$'s and β). Preliminary computations for argon on the basis of (3) have yielded fairly encouraging results; details of the method and results of numerical work based on (3), (5) and (7) will be reported elsewhere.

Improved Resolution of X-Ray Diffraction Patterns of Protein Crystals at Low Temperature

POSSIBILITIES for X-ray crystal structure analysis of proteins are limited by the minimum spacings observed in diffraction. For many proteins, the minimum spacing is about 2·5 A.—a limit which does not permit the resolution of individual atoms in Fourier maps prepared from the data, even if these are accurately measured, and the problem of the determination of the phases of the X-ray diffraction spectra can be solved successfully. This lack of resolution puts a severe restriction on the use of Fourier methods for structure determination of proteins. For a few proteins, such as bovine pancreatic ribonuclease, data with a minimum spacing of 1·5 A. are available, so that resolution of atoms is possible in principle. Thus the study of protein structure is highly dependent on fortune in obtaining crystals permitting atomic resolution in their diffraction effects.

An investigation of the causes of the limit on the minimum spacing should be of value in indicating possible ways of improving the situation, as well as in providing information about the nature of protein crystals. In general, the value of the minimum spacing is a measure of the average of the deviations of atoms from their mean positions in the structure; these deviations are due to types of disorder which might be either static or dynamic. Static disorder may appear as a result of heterogeneity (configurational or chemical) of the protein, or as a result of packing faults. Dynamic disorder is likely to be a complex phenomenon in protein crystals, involving restricted Brownian movement of the protein molecules about their mean positions, coupled with the surge of molecules of the solvent from one interstice to the next, in addition to the normal thermal vibration existing within each protein molecule. Brownian movement is likely to be greatest for mechanically weak protein crystals, in accord with experience at the Protein Structure Project with the minimum spacings observed for the various modifications of ribonuclease.

If the dynamic disorder is a large component of the total disorder within a protein crystal, the resolution of the diffraction should improve with decrease of temperature, with a limit on improvement, however, imposed by the tendency for 'freezing-in' of disorder at low temperatures, and the fact that the interstices will not, in general, hold an integral number of solvent molecules.

Low-temperature diffraction studies of crystals of ribonuclease II were made by Dr. Vittorio Luzzati (now at Centre de Recherches sur les Macromolecules, 6 rue Boussingault, Strasbourg, France) at the Protein Structure Project; these crystals had been grown from various aqueous alcohols[1]. He found that each crystal showed an abrupt increase in mosaic character at a temperature approximately equal to the freezing point of the pure solvent. This phenomenon is probably caused by disruption of the protein crystal as crystallites of the solvent are produced within the interstices, and precludes, of course, any improvement of resolution on further decrease of temperature.

The range from room temperature to the freezing point of the solvent is usually quite limited. The only recourse appeared then to be to replace the solvent within the interstices with another solution which does not freeze at the desired temperature of study. The investigation of low-temperature diffraction effects of protein crystals was resumed with the study of crystals of ribonuclease II which had been crystallized from 55 vol. per cent 2-methyl-2,4-pentanediol, and had then been soaked for one week in 90 vol. per cent 2-methyl-2,4-pentanediol. The latter composition was chosen as containing the minimum amount of water necessary for maintaining the ribonuclease crystals without visual or X-ray indications of damage. This solvent does not freeze, but becomes highly viscous at dry-ice temperature, and glassy at lower temperatures.

Two crystals were soaked as indicated, mounted in random orientations, and 5° oscillation photographs were taken at room temperature and at −27° C. Of these, the larger crystal showed an improvement at the lower temperature of the minimum observed spacing from 1·69 to 1·41 A., while the smaller showed a change from 1·81 to 1·66 A. On the average, then, the minimum spacing decreased by about 15 per cent. This corresponds to an increase in maximum observed length of reciprocal lattice vector of 15 per cent, or to 50 per cent greater volume covered in reciprocal space.

This degree of improvement of resolution, while not great enough to give a crucial advantage in crystal-structure determination, nevertheless indicates that the limitation on resolution is due at least in part to thermal disorder. It should be noted that ribonuclease crystals give much better resolution than do most protein crystals, and compare well even with simple organic structures, for which the minimum spacing observed is often 0·6–0·7 A. Hence, the room for improvement in resolution in diffraction results from ribonuclease is small. The technique of low-temperature diffraction studies will probably be of more practical benefit in the study of other protein crystals which do not give such good results at room temperature, and may in some cases make possible resolution of atoms in structures for which the room-temperature results do not permit this. In each case, however, it will be necessary to have within the interstices of the crystal a solvent which remains liquid at sufficiently low temperatures. For proteins which would be denatured by organic solvents, solutions of salts or salt mixtures having very low eutectic temperatures might be applicable.

I wish to thank Prof. I. Fankuchen and Dr. Judith Bregman and their co-workers for the use of low-temperature equipment and for invaluable aid and suggestions. Appreciation is expressed to the various institutions (the Dean Langmuir Foundation, the Rockefeller Foundation, the Damon Runyon Fund, New York Foundation, Inc., the Polytechnic Institute of Brooklyn, the International Business Machines Corporation) the continued support of which makes the work of the Protein Structure Project possible.

Separation of the Lower Fatty Acids (C_1 to C_{10}) by High-Voltage Paper Electrophoresis

Several paper-chromatographic procedures for the separation of the lower fatty acids as their ammonium or ethylamine salts have been described[1]. They suffer, however, from two disadvantages: formic acid cannot be separated from acetic acid and the time required is about 20 hr. By running the chromatograms at 50–60° C. the time required for the separation of the acids C_2 to C_6 could be reduced to 1–2 hr., according to a recent report[2].

During a study of the migration-rates of inorganic cations under high-voltage conditions[3], it was found that under identical conditions many inorganic anions[4] and the lower fatty acids were separable within 10–45 min. The separation of the isomers of C_4 and C_5, however, was not feasible, owing to the very small differences in mobilities. Fig. 1 shows the positions of the acids C_1 to C_{10} under the chosen conditions.

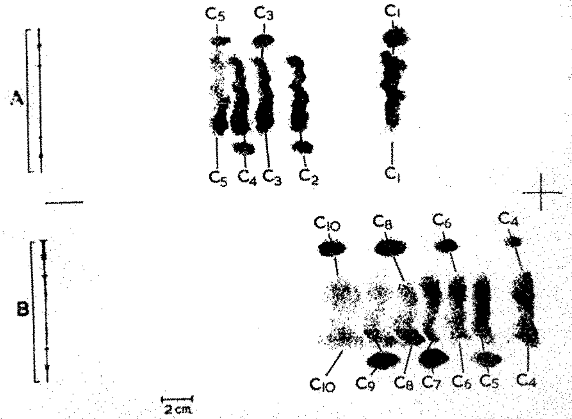

Fig. 1. Electrophoretic separation of the lower fatty acids (C_1 to C_{10}). Conditions: (*A*) 100 V./cm., 13 m.amp./cm., 1·5 lb./in.², Whatman No. 3 *MM*, 4 in. × 22½ in. strip, approx. 0·1 *M* ammonium carbonate solution (7·9 gm./l.), *p*H 8·9, mean temperature of cooling water 12° C., 20 min., applied 2 in. from cathode end 10–20 μgm. of each acid per spot and 50–100 μgm. per band; spraying reagent: 0·025 per cent bromophenol blue in acetone–water (9 : 1) mixture, acidified with 100 mgm. of citric acid per 100 ml. (*B*) as above, 45 min.

The sparingly water-soluble acids C_6 to C_{10} were converted into their sodium salts by dissolution in dilute sodium hydroxide, which did not affect their migration-rates. The acid radical migrates apparently as the free acid, finally forms the ammonium salt and is detected as such.

The first five or six members of the series can be separated within 20 min. at 100 V./cm. (*A*), the rest require 45 min. for complete separation (*B*). The electrograms were dried at 80° C. for about 10 min. and then sprayed with the bromophenol blue reagent, producing blue spots on yellow background stable under ordinary laboratory conditions for at least several hours and of a sensitivity of 2–5 μgm. according to the acid. A more sensitive reagent was found in a solution of 0·05 per cent bromocresol purple in 90 per cent ethanol, with a sensitivity of 0·5–1·0 μgm. for most of the acids but producing rapidly fading colours. The reagent, however, proved useful in the detection of the presence of the faster migrating inorganic anions, for example, chloride and sulphate, in mixtures of fatty acids.

The complete separation of the mixture allowed a convenient quantitative determination of the individual components based on the roughly linear relationship between spot area and concentration over a range of 5–25 μgm. An interesting feature of the paper electrophoretic behaviour of the lower fatty acids is that the mobilities are inversely proportional to the molecular weights, causing a sequence of migration similar to that in vapour-phase chromatography[5] but the reverse of that in paper chromatography. This effect can be utilized for checking doubtful separations by a two-dimensional combination of paper electrophoresis and paper chromatography. There is apparently little correlation between the dissociation constants of the acids and their mobilities, except for the pair formic and acetic acids.

Thanks are due to Mr. H. C. S. de Whalley, director of research, for his interest, Mr. R. W. Butters for technical assistance, and the directors of Tate and Lyle, Ltd., for permission to publish this communication.

The Basicities of N-Alkyl Anilines

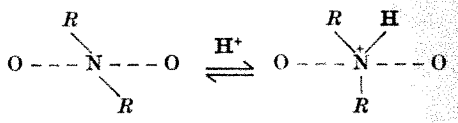
THE order of the basicities of the N-alkyl anilines, for which no satisfactory explanation has hitherto been proposed, can be accounted for by a consideration of the intramolecular overcrowding that occurs in the corresponding anilinium ions.

The observed order of basicities[1], measured in water at 25° C. is :

	pKa		*pKa*
Aniline	4·62	Dimethylaniline	5·98
Methylaniline	4·85	Diethylaniline	6·56
Ethylaniline	5·06	Di-*n*-propylaniline	5·59
n-Propylaniline	5·02	Di-*n*-butylaniline	5·7

The order of basicities is usually explained on the grounds of steric inhibition of resonance[2,3], but this fails to account for the large steric requirements of ethyl groups, and indeed has been criticized by Thomson[3].

The results can, however, be explained as follows :



(I) (II)

In the free base (I), the configuration of the molecule is a compromise between the steric requirements of the alkyl groups (*R*) and the coplanarity demanded by conjugation between the amino group and the benzene ring. The bulkier the alkyl groups, the greater the steric inhibition of resonance, and therefore the greater the basicity. On this consideration, pK_a should increase with increase in size of *R*. In the anilinium ion (II), however, conjugation is eliminated, and the configurational requirements of the ion forces one of the alkyl groups towards an *ortho* position. The larger the alkyl group, the greater the resulting instability of the anilinium ion ; thus the basicity will be reduced.

When *R* is a methyl or ethyl group, intramolecular overcrowding in the anilinium ion is small, and the increasing effect of steric inhibition of resonance in the free base gives an increased basicity on passing from *R* = methyl to *R* = ethyl. For the larger *n*-propyl and *n*-butyl groups, however, instability of the anilinium ion causes a fall in basicity, since no further increase in steric inhibition of resonance can occur.

A similar explanation has been given by Brown[4], using the terms '*B*-strain' and '*F*-strain', to account for the reduced basicity of dimethyl-*m*-2-xylidine over dimethyl-*o*-toluidine. In using these concepts to account for the reduced basicity of trimethylamine over dimethylamine, however, Brown[5] is on more difficult ground, since it is not valid[6] to make a direct comparison of the dissociation constants of primary, secondary and tertiary amines.

Infra-red Absorption Spectra of Casein and Lactose

A COMMUNICATION by Goulden[1], stating that an interaction between protein and sugar is demonstrated by the infra-red absorption spectra of mixtures of the two, prompted us to study this system in the hope that a similar approach might yield information about antibody–antigen reactions.

The spectrum of a dry intimate mixture of casein and lactose shows sharp bands between 7·0 and 11·0μ, whereas the spectrum of a freeze-dried solution of the same mixture shows broad diffuse absorption bands between these wave-lengths. As these differ-

ersity College

ences occur in a region of the spectrum associated with C—O stretching and O—H bending vibrations, Goulden suggested that the casein and lactose are held together either by some form of hydrogen bonding or by residual water molecules which are firmly bound between the protein and the carbohydrate molecules[2].

In the course of our work on the infra-red absorption spectra of mixtures of casein and lactose, it soon became obvious that there was little evidence for an interaction. An examination of the spectra of α-lactose monohydrate, anhydrous α-lactose, β-lactose and the glasses formed by evaporating aqueous solutions of these sugars showed that the glasses gave spectra with broad, poorly resolved bands, whereas samples of the same sugars examined as finely ground powders in mineral oil or in potassium bromide or chloride disks gave sharper and better resolved absorption bands (Fig. 1). This dependence of the spectrum of a sugar upon the physical state of the specimen has been reported by several workers[3-5]. It seems likely, therefore, that a large part of the difference in spectrum attributed to an interaction between casein and lactose is due to the lactose changing from the crystalline to the glassy (amorphous) state. This possibility is confirmed by two simple experiments. (1) The spectrum of a freeze-dried solution containing both casein and lactose can be reproduced by casting a film of lactose in the glassy state on one side of a silver chloride support and a film of casein on the other. (2) The change observed by Goulden can be reversed by exposing a film of casein and amorphous lactose to a humid atmosphere (relative humidity 75 per cent); under these conditions the amorphous lactose recrystallizes to the α-monohydrate. It may still be that there is some residual change in spectrum due to an interaction, but its magnitude is much less than that due to the change in the lactose.

The infra-red absorption spectra of pressed alkali halide disks containing sugar are liable to change during storage[4], and to minimize such changes we have followed the procedure recommended by Barker *et al.*[5]. Despite these precautions changes have been observed in the spectra of disks stored for several months. In particular, the conversion of anhydrous α-lactose to α-lactose monohydrate and β-lactose to α-lactose monohydrate can be followed by changes in the spectrum of the disk. Specimens of anhydrous α-lactose have to be handled with care because, when they are exposed to the laboratory atmosphere (relative humidity 60 per cent), the change to α-lactose monohydrate takes place in less than three hours.

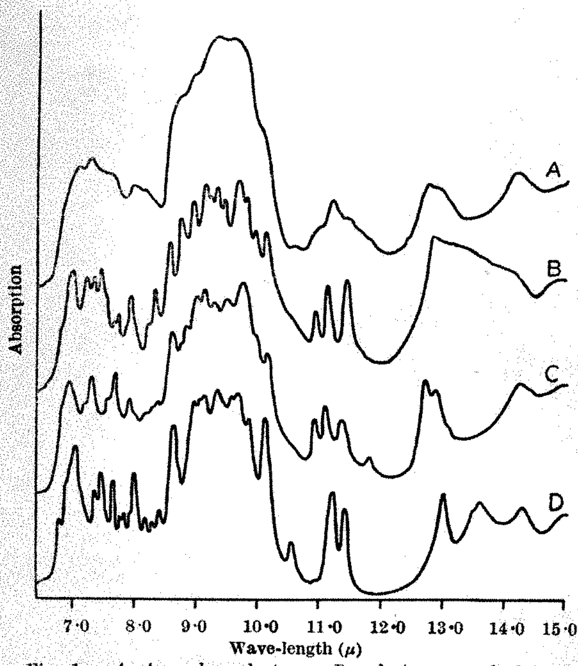

Fig. 1. *A*, Amorphous lactose; *B*, α-lactose monohydrate; *C*, anhydrous α-lactose; *D*, β-lactose. *A* is a glass-like film on silver chloride; *B*, *C* and *D* are potassium chloride disks

The physical state of lactose obtained by drying a solution of lactose depends upon the conditions of drying, the presence of materials other than lactose in the solution and their concentrations. The monohydrate of α-lactose crystallizes easily from solution at temperatures below 95° C., and the anhydrous sugar can be prepared by heating the monohydrate at 120–130° C.

The importance of the conditions of drying is indicated by the published spectra[2] of heat-dried full-cream milk and freeze-dried separated milk, which show bands typical of α-lactose monohydrate and the glass form respectively.

We wish to thank Mr. S. J. Lovett for making the sample of β-lactose; this had $[\alpha]_D^{19°} = 34°$.

Effects of Crystallinity on the Infra-red Absorption Spectra of Lactose and Dried Milk

In an earlier communication[1], it was shown that the infra-red absorption spectra of lactose–casein mixtures showed very marked changes after freeze-drying from aqueous solution. This was interpreted as indicating the presence of an interaction between the lactose and the casein. During the course of attempts to elucidate further the nature of this interaction, it has now been shown that these changes are due largely to the state of crystallinity of the lactose.

Fig. 1*a* shows the spectrum of crystalline lactose, obtained from a sample of the crystalline α-monohydrate. Fig. 1*b* shows the spectrum of amorphous lactose, obtained by freeze-drying a dilute aqueous solution, or by heat-drying a thin film of lactose solution on the surface of a barium fluoride plate. Examination with a polarizing microscope of the samples used for these spectra confirmed the presence of crystalline and amorphous material in the respective samples.

When saturated lactose solutions were used for freeze-drying, the lactose appeared in the crystalline

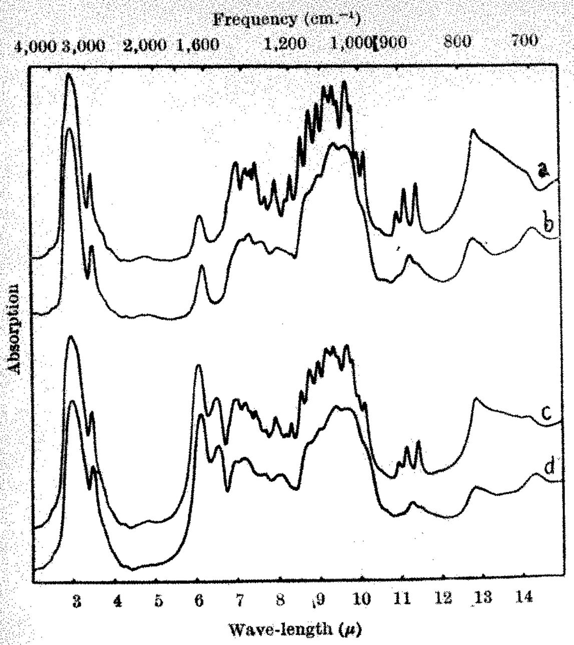

Fig. 1. Infra-red spectra of (*a*) crystalline lactose, (*b*) amorphous lactose, (*c*) 'soluble' dried separated milk, (*d*) dried separated milk

form, if the initial freezing stage was carried out too slowly. The effects of this can be seen in the spectrum 1*A* of ref. 1.

These results are of particular interest in the interpretation of the infra-red spectra of dried-milk samples, since the spectra of samples of dried separated milk made 'soluble' by the 'Instant' process[2] show that the lactose has been converted into the crystalline form (Fig. 1*c*). The spectra of samples which have been dried in the normal way show that the lactose exists in the amorphous form (Fig. 1*d*). Further confirmation of this change in the state of the lactose is afforded by freeze-drying solutions of 'soluble' milk powder, when the spectra are similar to Fig. 1*d*, showing that the lactose has reverted to the amorphous form.

The conversion of dry amorphous lactose to the crystalline α-monohydrate on exposure to atmospheric water vapour can be shown by the infra-red spectra, and similar changes can also be seen in the spectra of dried-milk samples under similar conditions.

The spectra were obtained with a double-beam Grubb Parsons *S3A* spectrometer fitted with a rock-salt prism, and the samples were examined using the potassium bromide pressed-disk technique. Similar results were obtained when the samples were examined by the 'Nujol' mull technique.

'Multiple' Hæmoglobins in the Horse

THE finding of electrophoretically distinct hæmoglobins in man has, in recent years, been followed by similar reports in animals. In cattle[1,2], for example, and in sheep[3], hæmoglobins have been discovered which seem to be inherited as simple allelomorphs.

Cabannes and Serain[1] examined the hæmoglobin of forty-eight horses by paper electrophoresis at alkaline *p*H. In forty-five samples the hæmoglobin resolved into two fractions moving at different speeds; in the remaining three only the faster-moving component was seen. We have examined hæmoglobin from sixty-five horses and found two fractions in sixty-four and only one, the fast-moving component, in one. Thus of 113 samples, 109 (96·5 per cent) were composed of two components, and four (3·5 per cent) showed only one, which was the fast-moving component in each.

If, as in cattle and sheep, the two hæmoglobins were allelomorphs, this result would represent a remarkable example of hybrid vigour. We decided, therefore, to re-investigate the one horse in which we had found only one hæmoglobin. By the use of starch or agar zone electrophoresis, in which larger quantities of protein can be used, it was found that this specimen also consisted of two hæmoglobin fractions. But, whereas usually the quantity of slow to fast is 0·67 : 1, in this particular horse it was 0·25 : 1. By using thicker paper and more hæmoglobin, the slow fraction could be demonstrated also by paper electrophoresis.

We were thus satisfied that in our series of sixty-five specimens two fractions were present in all, and that this distribution strongly indicated the presence of 'multiple' hæmoglobins in the horse rather than that of two allelomorphs.

We have another indication that the two horse hæmoglobins are not allelomorphs, as it seems that mules and jennets do not inherit one but both these hæmoglobins. Cabannes and Serain[1] had shown that donkeys possess one hæmoglobin and that mules may possess two. Of four mules, two showed a hæmoglobin pattern not unlike that of the horse, and in two, paper electrophoresis demonstrated only one, the slow-moving fraction. In fourteen specimens from donkeys, we have found only one fraction which moved slightly faster than the 'slow' horse fraction. On examining blood from nineteen mules and three jennets, each one was found by us to be resolved into two fractions, of which the faster amounted to about 38 per cent; neither fraction moved exactly in coincidence with those of the horse hæmoglobin (Fig. 1). When donkey hæmoglobin

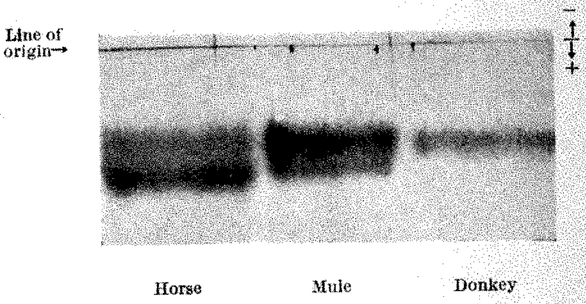

Fig. 1. Paper electrophoresis at *p*H 8·6 of horse, mule and donkey hæmoglobin ('hanging strip' technique, ref. 4). Compared with the two fractions of the horse, the 'slow' component of the mule hæmoglobin moves a little faster, and the 'fast' component more slowly. The single band seen in the donkey hæmoglobin does not coincide with any of the other four

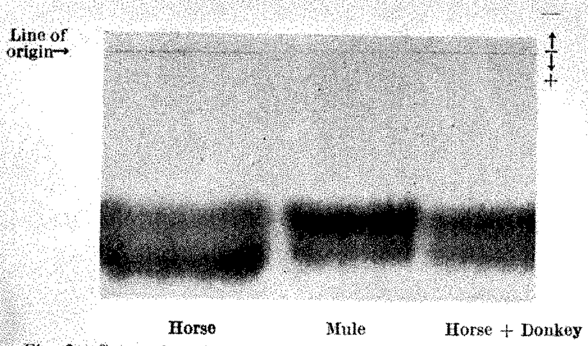

Fig. 2. Comparison by paper electrophoresis at pH 8·6 of the hæmoglobin of horse and mule, and of a mixture from horse and donkey ('hanging strip' technique, ref. 4). The mixture of horse and donkey hæmoglobins resemble mule hæmoglobin in its electrophoretic behaviour. The 'fast' component of the horse pigment moves in this mixture like the 'fast' component in the mule

was added to horse hæmoglobin so that the proportion of the 'fast' horse component was 38 per cent of the total, then the mixture showed an electrophoretic pattern identical with that of mule or jennet hæmoglobin (Fig. 2). When the fast-moving fraction of mule hæmoglobin or of the donkey/horse mixture was eluted and added to an eluted solution of 'slow' horse hæmoglobin, this mixture produced a pattern identical with that found in horse. Although we have not achieved a resolution of mule and jennet hæmoglobin into three fractions (one donkey and two horse hæmoglobins), it seems to us that there is circumstantial evidence that three hæmoglobins are in fact present.

We wish to acknowledge the help of the following in obtaining samples of blood: Dr. R. K. Archer, Equine Research Station, Newmarket; Capt. H. W. Bishop, R.A.V.C., Hong Kong; Dr. S. L. Hignett and Mr. J. Scarnell, Wellcome Veterinary Research Station, Frant; Prof. J. A. Nicholsen, Veterinary College of Ireland, Dublin; and Mr. D. Russel, Tipperary.

The Diego Blood Group System

In previous communications we reported the presence of the blood group antigen Di^a in Chippewa Indians in North America and in Japanese[1], and its absence in 156 Eskimos of the eastern Canadian Arctic[2]. Since then Layrisse and Arends[3] and Junqueira and Wishart[4] have reported the absence of Di^a in 107 and in 150 pure blood Negroes, while Simmons[5] has reported its absence in 80 eastern Polynesians, 162 Australian aborigines, 23 Papuans and 74 natives of New Britain.

We have now had an opportunity of studying, through the kindness of Dr. Eric Nation of the Canadian Red Cross Blood Transfusion Service, 50 specimens from Blood Indians living in southern Alberta, finding 3 to be $Di(a+)$, while Dr. J. Hildes, of the Department of Physiology and Medical Research of the University of Manitoba, recently collected for us another 68 specimens from Eskimos of the eastern Canadian Arctic; like the first 156, these were all $Di(a-)$. Dr. Hildes's specimens were distributed as follows: east central Baffinland 49, south Baffinland 11, south shore of Davis Strait 8. The Blood Indians were not selected to rule out close relatives whereas the Eskimos were.

Layrisse and Arends[6] found 5 of 100 Chinese (5 per cent) and 8 of 65 Japanese (12·3 per cent) to be $Di(a+)$; we[7] found 10 out of 145 Japanese (6·9 per cent) to be $Di(a+)$, while Dr. Mitsuo Yokayama of the Blood Typing Laboratory, University of Tokyo, informs us that he has found the percentage in Japanese to be 5–7. It seems probable that Di^a is about as common both in large Asiatic and large American Indian populations as *Kell* is in Whites; no high-frequency area for *Kell* has been reported which compares with the high frequencies found in certain South America Indian tribes by Layrisse and Arends[8] and by Junqueira *et al.*[9]. The apparent absence of Di^a in Eskimos of the eastern Canadian Arctic continues to intrigue us.

Our studies have been supported by the National Museum of Canada.

Separation of Carotenoid Synthesis from Fat Synthesis in *Rhodotorula gracilis* by Diphenylamine

In the fat-synthesizing red yeast *Rhodotorula gracilis* Rennerfelt fat synthesis occurs simultaneously with carotenoid synthesis. Since Turian[1] and Goodwin[2] found that carotenogenesis in *Mycobacterium phlei* and in *Phycomyces blakesleeanus* can be inhibited by diphenylamine, we thought it of interest to see whether carotenoid and fat synthesis in *R. gracilis* might be separated by the action of diphenylamine.

The cells of *R. gracilis* were grown aerobically at 25° C. for three days in a synthetic medium[3] containing various amounts of diphenylamine. The concentrations of diphenylamine tested and the final dry-weight determinations of the cells are given in Table 1. The results show that with up to 45 mgm. of diphenylamine in 1,000 ml. of the cultivation medium there is no inhibition of growth of *R. gracilis* to be noted, although it could be observed that the colour of the cells diminished gradually with increasing concentrations of diphenylamine. With 40 and 45 mgm. diphenylamine in 1,000 ml. medium, the cells are colourless and do not contain any

Table 1. EFFECTS OF DIPHENYLAMINE ON THE GROWTH OF *Rhodotorula gracilis*

Mgm. diphenylamine in 1,000 ml. medium	Dry weight of cells in 10 ml. medium
0	71·2
5	70·5
10	70·8
20	71·0
30	70·2
40	69·8
45	69·5
50	1·2

Table 2. FAT CONTENT OF CELLS OF *Rhodotorula gracilis*, GROWN IN THE PRESENCE OF DIPHENYLAMINE

Mgm. diphenylamine in 1,000 ml. medium	Per cent fat in the dry weight of the cells
0	60·5
5	61·0
30	59·8
45	57·0

carotenoids. In these conditions, however, the fat synthesis is not impaired, as shown by fat content determinations (cf. Table 2). Even with the highest concentration of diphenylamine, namely, 45 mgm. in 1,000 ml., the fat content of the cells is only insignificantly decreased.

In agreement with Goodwin[2], we found the inhibitory action of diphenylamine towards carotenogenesis to be irreversible in a certain sense. When the cells of *R. gracilis* are grown in a medium containing diphenylamine and then, after centrifugation and washing, are transferred into a medium which contains neither diphenylamine nor a nitrogen source, where under normal conditions carotenoid synthesis can take place, the cells remain colourless. If, however, the cells treated with diphenylamine are transferred into a medium containing a nitrogen source and thus are allowed to proliferate, they gradually recover their capacity of carotenoid synthesis.

Preparation of Transparent Starch Gels after Electrophoresis

IN the method of electrophoresis on starch gel recommended by Smithies[1], the gels obtained after the electrophoresis and staining of proteins are opaque, difficult to preserve and not suitable for photometric evaluation. For this reason we have devised a technique for preparing starch gels which remain transparent after staining.

Since a protein dye in alcoholic solution, for example, a saturated solution of amidoschwarz in 10 per cent acetic acid in methanol, results in a permanently opaque gel, we prefer to use the dye in aqueous solution; 1 per cent amidoschwarz in a sodium acetate/acetic acid buffer (sodium acetate 0·1 *M*, 450 ml., acetic acid *M*, 450 ml., amidoschwarz, 1 gm.), being used for staining in agar electrophoresis[2].

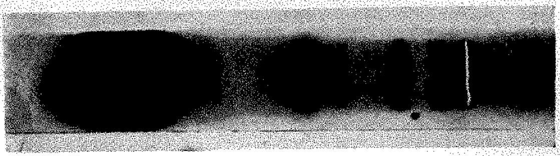

Fig. 1. Transparent starch gel after electrophoresis (human serum)

After fixing for one night in 5 per cent aqueous acetic acid the bands are stained for 10 min. and decolorized by successive washings in 5 per cent aqueous acetic acid. This washing should be prolonged (nearly 48 hr.).

A completely transparent starch gel can be obtained in the following way. A 1-mm. transverse section of stained starch gel is placed on a plate of photographic glass which has been covered with a film of melted agar and then dried in an oven. The glass plate is placed in a rectangular basin and a 1·50 per cent solution of melted agar is poured over it. After the agar has solidified the glass plate carrying the starch electrophoresis included in agar is withdrawn and a sheet of paper (Arches 302 or Whatman No. 1), is applied to the surface so as to regularize the evaporation and to absorb the non-volatile mineral salts. It is left to evaporate in an oven at 37° C. After 48 hr. a transparent film is obtained permitting the photometric evaluation of the different protein fractions of the serum (Fig. 1).

Reversal of Thymine Xyloside Inhibition in *Escherichia coli* by Glutathione

AN unexpected competitive relationship between thymine xyloside and glutathione has been found. Thymine xyloside inhibits the growth of *Escherichia coli* in a synthetic medium. This inhibition is competitively reversed by glutathione.

A wild-type *E. coli* (ATCC 26) was grown in brain-heart infusion broth for 6 hr. at 37° C., then diluted to 1/50,000 in a synthetic medium of the following composition: sodium phosphate 0·6 per cent, acid sodium phosphate 0·3 per cent, ammonium chloride 0·1 per cent, sodium chloride 0·1 per cent, magnesium sulphate 0·01 per cent, potassium chloride 0·3 per cent, glucose (autoclaved separately) 0·4 per cent. The size of the inoculum in these conditions was about 5×10^4 cells per ml. The inoculated medium was pipetted into sterile 13 mm. × 100 mm. test tubes and the thymine xyloside or reversing agents added in seeded synthetic medium. The tubes were incubated overnight at 37° C., and the presence or absence of growth was determined by visual inspection. The minimum concentration of inhibitor to prevent growth completely was recorded.

The minimum inhibitory concentration of thymine xyloside varied with the preparation used. The best preparation gave an end-point of 1 μgm./ml. in these conditions. However, the reversal experiments were carried out with a preparation of inhibitor which gave an end-point of 6·4 μgm./ml. and were confirmed with the more active material.

Table 1. GROWTH INHIBITION OF *E. coli* BY THYMINE XYLOSIDE AND ITS REVERSAL BY GLUTATHIONE

Thymine xyloside concentration (μgm./ml.)	Glutathione concentration necessary to reverse inhibition (μgm./ml.)	Ratio
100	12·3	8/1
33	3·2	10/1
10	0·8	12/1

In a search for a possible reversing agent, glutathione was tried. This proved extremely effective in reversing the inhibition. About 0·1 mole of glutathione reversed 1 mole of thymine xyloside and this reversal was competitive (Table 1).

Reversal studies with purine and pyrimidine bases and nucleosides revealed no significant effects of these compounds. Fair reversal was obtained with technical casamino-acids ('Difco'). A survey of amino-acids revealed no single one which was as active as the casamino-acids. No agent was found which was as effective as glutathione in reversing the inhibition.

This competitive relationship between thymine xyloside and glutathione is quite interesting, and there is no apparent simple biochemical explanation for it. Beltz and Visser[1] have commented that 5-substituted deoxyribosyl-pyrimidines are the only substituted nucleosides which inhibit the growth of micro-organisms not requiring purines and pyrimidines for growth. Since thymine xyloside is a 5-substituted nucleoside with an unnatural sugar, it may be inhibiting in an analogous manner. It might be possible to use thymine xyloside to induce glutathione deficiencies so that glutathione metabolism and function can be more readily studied.

The thymine xyloside used in these studies was prepared by the method of Fox *et al.*[2] and was kindly supplied by Dr. J. H. Hunter of these Laboratories. Dr. Seymour Cohen has given helpful advice and encouragement.

Aerobic Inhibition of Glycolysis

DURING investigations on the synthesis of sucrose from glucose-1-phosphate and fructose by pea seed extracts it was observed that a glycolytic system was operating in the enzymic digests[1,2]. The pea extract had been partially purified by precipitation with ammonium sulphate (80 per cent saturation) and dialysis against phosphate buffer at *p*H 7·0. It was found that there were differences in glycolytic activity when the enzymic digests were incubated under aerobic and anaerobic conditions.

When digests containing glucose-1-phosphate and fructose were incubated in air there was a small increase in inorganic phosphate after 40 hr. (Table 1). In nitrogen the inorganic phosphate decreased. Visual examination of the phosphoric compounds of the digest samples on paper chromatograms developed in *n*-propyl alcohol/ammonia/water (60 : 30 : 10, v/v) and *tert*-amyl alcohol/water/formic acid (90 : 90 : 30, v/v)[3] confirmed this decrease in inorganic phosphate and showed that extra phosphoric esters accumulated in nitrogen. This accumulation appeared to be largely due to increases in fructose-1,6-diphosphate, hexose monophosphates and a substance running in a position similar to adenosine triphosphate. Incubation of the enzymic digests *in vacuo* gave similar results to those obtained in nitrogen.

Table 1. EFFECT OF ANAEROBIC CONDITIONS ON INORGANIC PHOSPHATE CONTENT

Gas phase	Inorganic phosphate (μmoles/ml. digest)	
	0 hr.	40 hr.
Air	9·5	11·5
Nitrogen	9·5	2·2

Digest: glucose-1-phosphate, 0·0144 *M*; fructose, 0·0244 *M*; $MgCl_2$, 0·01 *M*; yeast nucleotide fraction, 0·5 ml.; partially purified pea extract, 1 ml.; total volume, 1·8 ml. *p*H 7·0, 25° C.

Table 2. EFFECT OF ANAEROBIC CONDITIONS ON FRUCTOSE LOSS

Gas phase	Fructose (μmoles/ml. digest)	
	0 hr.	20 hr.
Air	24·4	10·1
Evacuated	24·4	0

Digest: as in Table 1.

Anaerobic conditions also accelerated the decrease in fructose in the enzymic digests (Table 2). Fructose had disappeared after 20 hr. under anaerobic conditions, whereas in air a considerable quantity of this sugar remained.

When the gas exchange of the enzymic digests was examined, it was found that in air there was a barely significant oxygen uptake suggesting that oxidative processes were not proceeding to an appreciable extent. There was a considerable carbon dioxide output in air, and this was increased markedly in an atmosphere of nitrogen.

The effect of oxygen on the enzymic digests may be analogous to the Pasteur effect, for which a number of explanations have been proposed[4-6]. If so, the results obtained in the present investigation may support the hypothesis of Lipmann[7] that oxygen inhibits glycolysis by inactivating one or more of the glycolytic enzymes. In the simple system investigated here (which is not complicated by the existence of respiratory processes) glycolysis is the only source of adenosine triphosphate or energy-rich phosphate bond. It seems probable that the rate of hexose utilization is decreased under aerobic conditions because of a decreased production of adenosine triphosphate and this may in part be due to a partial inactivation of one of the glycolytic enzymes.

Formation of Histamine-containing Dinucleotides by Enzymatic Interaction of Histamine and Coenzyme I

DIPHOSPHOPYRIDINE nucleotide (coenzyme I) reacts, in the presence of a soluble purified preparation of diphosphopyridine nucleotidase[1], with 4-amino-5-carboxamido-imidazole yielding the pyrophosphate of adenosine-5′-phosphate and of the 4-amino-5-carboxamido-imidazole ribotide[2,3]. The latter may serve as a precursor in the biosynthesis of inosinic acid[4].

It was of interest to study the influence of various side-chains attached to carbons number 4 and/or 5 upon the ability of the imidazole to participate in such diphosphopyridine nucleotidase catalysed reactions. Histamine was selected as a first example.

In a typical experiment (Table 1) histamine (252 µmol.), diphosphopyridine nucleotide and diphosphopyridine nucleotidase (21 units[1]) were incubated in a volume of 0·25 ml. at 38° C. at an initial *p*H about 8·0 for 4 hr. The *p*H was maintained relatively constant by means of the proper ratio of histamine (free base, 157 µmol.) to histamine dihydrochloride (95 µmol.). This ratio was calculated from the *pK* values of the histamine mono- and di-hydrochlorides (9·7 and 6·0 respectively). Sample number 3 (Table 1) was buffered with *tris*-hydroxy-methyl-amino-methane to *p*H 8·0.

Normally, two molecules of *d*-ribose and two molecules of organically bound phosphate[5] correspond to every coenzyme I molecule, measured by means of the alcohol dehydrogenase[6] and the cyanide[7] techniques. It was found that the amount of *d*-ribose, as measured by conversion to furfural in the presence of orcinol[8], diminished as the incubation proceeded, and tended to reach one-half of its original value (Table 1). However, periodate oxidation used for quantitative determination of vicinal *cis*-hydroxyls (*cis*-glycols)[9], represented by the 2,3-alcoholic hydroxyls of the *d*-ribose, indicated that their number per mol. of coenzyme I remained constant during incubation and was the same as the number of organically bound phosphate groups (Table 1).

In order to separate the products of this reaction, coenzyme I (340 µmol.) and diphosphopyridine nucleotidase (280 units) were incubated with carbon-14 2-(ring)-labelled histamine (500 µc., 2,000 µmol. of the described mixture of the free base and its dihydrochloride). The initial *p*H was approximately 8·0 and the total volume was 4 ml. Upon consumption of all the coenzyme I present (16 hr., 38° C.), the mixture was passed through a 'Dowex' 1 × 10, chloride form, column.

The main product of the reaction, a dinucleotide (dinucleotide I), was eluted with 0·00025 *N* hydrochloric acid, *p*H 3·6. A second dinucleotide (dinucleotide II) was eluted from the column with 0·004 *N* hydrochloric acid, *p*H 2·4, in much smaller quantities (approximately a quarter of dinucleotide I).

Both dinucleotides I and II corresponded to the formula: Histamine–(ribose)–phosphate–phosphate–ribose–adenine. For as yet unknown reasons, the ribose moiety placed in the formula in parenthesis was not reactive in the orcinol test[8]. Both dinucleotides I and II were radioactive (about 0·24 µc. per µmol.), gave positive ninhydrin tests (primary amines), and crystallized as picrates. They coupled with diazotized sulphanilic acid (yellow at *p*H 10, maxima at 402 mµ and 438 mµ respectively), and had characteristic absorption spectra in the ultraviolet. For example, at *p*H 2·0, dinucleotide I showed two maxima, at 257 mµ and 208 mµ, and a minimum at 234 mµ. Dinucleotide II at the same *p*H, besides the maximum at 257 mµ, had a shoulder at about 208 mµ. Organic pyrophosphatase[10] split both dinucleotides I and II into adenosine-5′-phosphate[3] and a histamine–(ribose)–phosphate moiety (mononucleotides I and II). Ascending R_F values in the system alcohol/0·1 *M* acetic acid (1 : 1)[6] were 0·53 and 0·68 for dinucleotides I and II respectively; 0·69 and 0·76 for mononucleotides I and II respectively.

Electrophoretic studies[3] were conducted in ammonium formate, *p*H 3·6 and *tris*-hydroxy-methyl-amino-methane, *p*H 7·6, at concentrations that showed specific resistance of 210 ohms at 4° C. and potential differences of 10 volts per cm. At *p*H 7·6 dinucleotide I and mononucleotide I moved towards the positive electrode and covered the same distance as coenzyme I, while dinucleotide II and mononucleotide II covered about twice the distance in the same direction. The mobility of the latter compounds was similar to that of adenosine-5′-phosphate at the same *p*H. At *p*H 3·6, dinucleotide I had zero mobility, while mononucleotide I moved towards the negative electrode. Dinucleotide II moved towards the positive electrode and mononucleotide II had zero mobility.

From the analytical results and the action of organic pyrophosphatase, it was concluded that dinucleotides I and II, like coenzyme I, possessed two negative charges at both *p*H 3·6 and 7·6, and mononucleotides I and II, like adenosine-5′-phosphate, possessed two negative groups at *p*H 7·6, and one at *p*H 3·6. Therefore, the above-mentioned mobilities might indicate that dinucleotide I had a pentavalent nitrogen structure which retained its positive charge at both *p*H 3·6 and 7·6 while dinucleotide II lacked such a structure. Both dinucleotides I and II had an additional positive group fully ionized at *p*H 3·6 (probably the aliphatic amine). The presence of a pentavalent nitrogen structure in dinucleotide I and of a trivalent nitrogen structure in dinucleotide II indicated a combination of either the basic or the pseudo-acidic forms of the imidazole[11] with (ribose). This may have resulted from changes in the *p*H

Table 1

rsity College of S

(from pH 8·0 to about 6·0) during the enzymatic reaction. Such pH changes can be tolerated by the enzyme[1,12].

Under our conditions the enzymatic reaction appeared to proceed completely towards the formation of the new dinucleotides. Nicotinamide inhibited this reaction.

Since histamine may be released in tissues[13] and in view of the wide distribution of diphosphopyridine nucleotidases of the glycosidase type similar to the one used in these experiments, it is possible that the reaction described may be involved in the mechanism of anaphylactic shock. Experiments are under way to test this possibility.

I am indebted to Dr. Israel Davidsohn, director of research, and Dr. Kurt Stern, associate director of Mount Sinai Medical Research Foundation, Chicago, for their interest in this work.

Accumulation of α-Alanine and of Pyruvate in Diphtherial Culture Filtrate and its Relation to Iron Deficiency of Medium

It was shown by Linggood and Woiwod[1] that marked changes, particularly an increase in the quantity of α-alanine, occurred in the chromatograms of a casein hydrolysate medium before and after the growth of a strain of *C. diphtheriae* under conditions favourable for toxin production. While studying the effect of iron on the amino-acid metabolism of a strain of *C. diphtheriae* in a simplified, chemically defined medium developed in our laboratory[2,3], we have also found that several amino-acids, especially α-alanine, appear and accumulate in the culture filtrate when the medium is deficient in iron. In further experiments, it has also been demonstrated that an accumulation of pyruvate takes place under the same conditions, and that the amounts of α-alanine and pyruvate appearing in the filtrates, decrease with the increasing iron content of the medium.

Small inocula of the four-day-old pericle of a variant (*SM*-1) of Park Williams No. 8 strain were grown on AMC media[2] containing varying amounts of iron. After four days of still incubation, the whole cultures were harvested and centrifuged at 4,000 r.p.m. for 30 min. The precipitated cells were washed three times with saline before measuring the bacterial nitrogen by a modified micro-Kjeldahl method, while the clear supernatants were used as materials for paper chromatography and also for the estimation of toxin by flocculation reactions, and of the pyruvate by the method of Friedmann and Haugen[4]. For the quantitative determination of α-alanine, the following method was used: Tōyō filter paper No. 50 was spotted with an aliquot of the supernatant, which had been boiled at pH 4·6, and then developed with phenol/water (4 : 1 v/v) and butanol/acetic acid/water (4 : 1 : 1 v/v/v) by the ascending technique. The part of the paper corresponding to the location of α-alanine on the two-dimensional chromatogram was cut to pieces and placed in a test tube. After complete colour development according to Fowden[5], the disrupted papers were removed by centrifugation at 3,000 r.p.m. for 2 min. and the colour intensity of the clear supernatant was then measured at 570 mμ with a Coleman-type spectrophotometer.

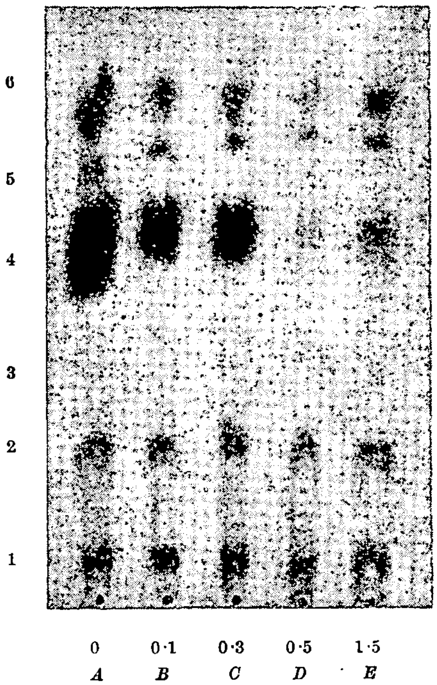

Fig. 1. One-dimensional paper chromatogram of supernatants harvested from diphtherial cultures grown with varying amounts or iron. 1, Aspartic acid and lysine group; 2, glutamic acid and cystine group; 3, asparagine, glycine and serine group; 4, α-alanine; 5, valine; 6, methionine, leucine and *iso*leucine group. μgm. of iron added per litre of medium: *A*, none; *B*, 66; *C*, 200; *D*, 330; *E*, 1,000. Solvent used: phenol/water (4 : 1 v/v)

From the accompanying photograph, showing a typical one-dimensional paper chromatogram of the culture filtrates, no major differences can be seen in the amino-acids present in each filtrate; however, the quantity of each amino-acid, particularly of α-alanine, varies with the amount of iron added to the medium. Quantitative results, showing the effect of iron on both α-alanine and pyruvate accumulations, are given in Table 1. Although the medium used in this experiment was not completely free of iron, added iron had a remarkable effect on the formation of α-alanine and of pyruvate by the diphtheria bacillus. It can be seen in Table 1 that the amounts of both α-alanine and pyruvate detected in culture filtrates at the end of incubation markedly decrease with the increase of iron added. Thus, for example, the quantity of pyruvate produced by the organism in the presence of 330–660 μgm./l. of added iron is

Table 1. EFFECT OF IRON ON THE FORMATION OF α-ALANINE AND PYRUVATE BY A STRAIN OF *Corynebacterium diphtheriae*. FOUR-DAY STILL-INCUBATION AT 32–33° C.

Iron added (μgm./l.)	Bacterial growth (μgm. N/ml.)	Toxin (Lf./ml.)	Pyruvate formed (μgm./ml.)	Alanine formed (μgm./ml.)
0	543	60	220	617
16·5	592	55	196	547
33	561	52	172	553
66	634	44	95	373
100	627	47	120	313
133	561	23	57	307
330	546	3	11	127
660	563	0	11	97

almost one-twentieth of the quantity formed in the absence of iron. A similar variation will be seen in the amounts of toxin and α-alanine formed.

Although the primary metabolic sequence affected by iron deficiency still remains uncertain, these results clearly indicate that traces of iron exert a distinct influence not only on the liberation of toxin but also on the pyruvate metabolism of the organism. Our previous work[6] has shown that significant quantities of glutamate–pyruvate transaminase were present in the cell-free extracts of *SM*–1 culture. Consequently, the accumulation of pyruvate due to iron deficiency may result in the appearance of large amounts of α-alanine in the filtrates. Further work is now in progress, and the details will be published elsewhere.

Thyroxine Metabolism by Extracts of Rat Liver

THE *in vitro* de-iodination of thyroxine has been reported in a variety of biological systems, including slices, homogenates, and extracts of mammalian organs[1–3]. In particular, a system present in rat liver has been fairly extensively investigated and a technique evolved whereby quantitative measurements of de-iodination can be readily obtained[4]. At the outset of the present work, this technique was employed to re-investigate the properties of the de-iodinating system of rat liver. The heat stability of the homogenate[3] and the heat lability of the extract were confirmed, and the system shown to be inhibited by potassium cyanide. The rate of de-iodination was fastest at the beginning of the incubation period and fell off with time, levelling off after 1–2 hr. when 50–70 per cent de-iodination had occurred. Substrate specificity was not absolute, tri-iodothyronine being metabolized to a lesser extent. In all these respects the system used resembles that previously described by other workers[4].

All these preliminary experiments employed thyroxine labelled with iodine-131 in the 3′ : 5′ positions and chromatography of the incubation mixture failed to reveal any radioactive metabolites apart from iodide and a varying amount of excess thyroxine. Such chromatograms were frequently run together with a marker of stable tri-iodothyronine, but no trace of this compound could be identified among the labelled reaction products. It seems likely, therefore, that the two iodine atoms in the 3′ : 5′ positions are removed simultaneously, or very nearly so. It was thereupon decided to synthesize radioactive thyroxine labelled with iodine-131 in the 3 : 5 positions, and to trace the metabolic fate of these atoms in the same system. It was immediately apparent from the first trials that de-iodination from these positions was slight; 80–95 per cent of the radioactive label remained adhering to the protein of the extract, and was thus presumably still in organic combination, iodide passing through the filter. An experiment was also carried out in which the samples of thyroxine contained the label in varying proportions on the two rings. The results show a proportionality between the extent of de-iodination and the percentage of the label present in the 3′ : 5′ positions.

Percentage of label in 3′ : 5′ positions	De-iodination (per cent)
0	8·0
20	19·5
40	29·9
60	35·0
80	43·6
100	53·9

Thyroxine is thus apparently metabolized to a compound (or compounds) which contains the 3 : 5 iodine atoms but from which the 3′ : 5′ iodine atoms are absent. Work which is still in progress indicates that this unknown compound can be separated from excess thyroxine by butanol extraction. Its chemical structure is apparently such that the alanine side-chain and proximal ring are preserved intact, because, on treatment by hydrolytic procedures, a labelled degradation product is obtained having the chromatographic properties of 3 : 5 di-iodotyrosine.

This work was undertaken during tenure of a grant from the Rockefeller Trust of the Medical School, and with facilities granted by the Medical Research Council.

The Biuret Complex of Gelatin and the Mechanism of Gelation

THE gelation of gelatin results from a thermally reversible cross-linking process involving hitherto unknown functional groups. In studies of gelation–molecular weight correlations of chemically modified gelatins (amino-acetylated, carboxyl-esterified, hydroxyl-acetylated, guanidino-nitrated) and of hypobromite-treated gelatin we have found that the polar and charged side-chain groups are of little importance in gelation[1]. Further, by study of the effects of various electrolytes on the melting points of gels of gelatin and of chemically modified gelatins, we have found that binding of ions at the polar and charged side-chain groups is not the mechanism by which electrolytes affect gelation[2]. These results have directed our attention to the role of the peptide group.

By the use of the well-known biuret reaction, we now show that the peptide group plays an important part in gelation. Formation of the biuret complex of gelatin with as little as 0·03 *M* copper (II) or cobalt (II) chloride in 5 per cent gelatin (peptide group to metal ratio 17) at *p*H 10–12 caused reversible suppression of gelation. Such solutions did not gel at 0°. However, they did gel, almost instantaneously, at 0° on destruction of the complex and the characteristic violet-red colour ($\lambda_{\text{max.}}$ 550) by acetic acid, sodium cyanide or ion-exchange resin. The melting point of the decomplexed gel was 27°, while those of ordinary gels of the same concentration at *p*H 3–12 are 28–30°. Inhibition of gelation by alkaline copper is, therefore, caused by complex formation and not by the high *p*H or by hydrolysis. The gelation on destruction of the complex is a property of the gelatin, and is not caused by copper or cobalt ions, as was shown by independent experiments in which the metals were removed by ion-exchange or dialysis. Copper and cobalt in alkaline solution are the most effective melting-point reducers found so far. By comparison, sodium thiocyanate and lithium diiodosalicylate[2] in 0·03 *M* solution lower the melting point of the gel by 0·5° and 4°, respectively.

Copper complexes of gelatins having amino- or hydroxyl-groups quantitatively acetylated[3], carboxyl groups 85 per cent methylated[4] or guanidino-groups 70 per cent nitrated[1] also did not gel at 0°, but did gel after destruction of the complex by acidification. These results show that the inhibition of gelation is due to the copper–peptide complex and not to side-chain complexes.

There are several ways in which formation of the copper–peptide complex may prevent gelation. One is by blocking peptide groups that normally engage in cross-linking through hydrogen bonds. A second is by inhibiting a required configuration either by blocking the peptide groups which maintain the configuration through hydrogen bonding or by forming 'knots' that disrupt the configuration. The 'knots' may also prevent gelation by steric interference with intermolecular association. A combination of these causes may be operative.

Although inhibition of gelation of gelatin requires only one copper or cobalt ion per seventeen peptide groups, actually a larger portion of the peptide groups is complexed, since in biuret type complexes of $\lambda_{\text{max.}}$ 550 three or four peptide groups are linked to one metal atom. For example, the lowest polyglycine to give the complex is triglycylglycine, while dialanylalanine gives only a weak reaction[5]. Also, two copper atoms combine with the octapeptide leucylhexaglycylglycine[6], and one copper atom combines with two molecules of biuret[7]. Thus, the complexation of $\frac{1}{6}$–$\frac{1}{8}$ of the peptide groups appears adequate to prevent gelation, particularly as gelation of gelatin appears to involve not the random association of pairs of functional groups but of a number of groups in ordered segments or crystallites[8,9]. The maximum copper binding by gelatin has been reported as one to about six peptide groups[10], which we have confirmed. The ratio of four cannot be realized because of the proline and hydroxyproline residues which contain no replaceable peptide hydrogen. The fluid, rather than cross-linked, nature of the complex shows that the binding is intramolecular.

Autoradiographic Visualization of Synthesis of Deoxyribonucleic Acid in Tissue Culture with Tritium-labelled Thymidine

THYMIDINE is a specific precursor of deoxyribonucleic acid[1]. The very low energy of tritium electrons permits precise localization on autoradiographs (within less than one micron on average) of the atom that disintegrates. This is not possible with other radioisotopes[2] such as phosphorus-32 or even carbon-14 or sulphur-35.

Tritium-labelled thymidine was prepared by hydrogen exchange between ordinary thymidine (California Foundation for Biochemical Research) and tritiated water in the presence of freshly reduced Adams's catalyst at 100° C. for 24 hr. After the catalyst had been filtered off and the tritium water removed by distillation, the residue was heated in 0·2 *N* sodium hydroxide so that only firmly bound tritium was retained; the solution was then neutralized with sulphuric acid and evaporated to dryness. The labelled thymidine was extracted with hot butanol, and, after treatment with charcoal, crystallized twice from butanol. White needles melting at 185°–186° C. (corr.) were obtained which gave the ultra-violet spectrum of pure thymidine. The radioactivity determined in an ionization chamber after combustion of the compound and reduction of the water to hydrogen was 14·9 mc. per millimole; it was exclusively localized in the pyrimidine moiety, as it was found entirely in the thymine isolated after hydrolysis of the labelled thymidine. A complete description of this preparation has been published elsewhere[3].

To hanging-drop cultures of chick fibroblasts prepared on a specially thinned medium, tritium-labelled thymidine (2×10^{-3} *M*) in tyrode solution was added, either from the time of explantation or later, for various periods. After excision of the original explants (leaving only the growth zone on the coverslip) and careful washings in Tyrode solution to remove the tritium-labelled thymidine present outside the cells, the cultures were fixed in 80 per cent ethanol. The coverslips were then mounted upside down on slides and stripping-film autoradiographs were made.

Development of these autoradiographs showed very low background and the cytoplasms were never

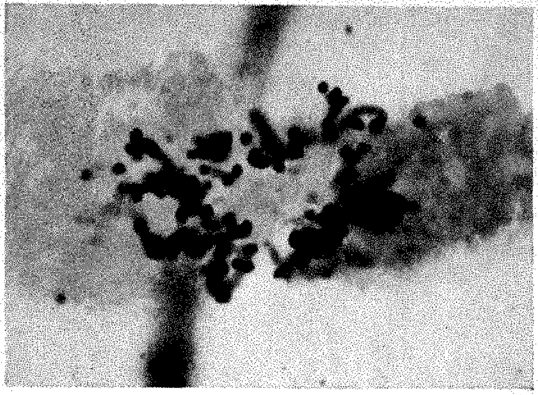

Fig. 1. Equatorial plate in a fibroblast. The chromosomes are grey. The sharp black dots are silver grains developed in the overlying autoradiographic film. × 2,100

labelled. Silver granules denoting the presence of tritium appear only over resting cell nuclei and on chromosomes in dividing cells (Fig. 1). The periphery of nucleoli often contains more grains than other areas of similar size in the nuclei. All labelled structures can be identified within less than 1μ, as already shown by Taylor, Woods and Hughes on another material[4]. The grains can be considered as indicative of the presence of tritium-labelled thymidine in an insoluble form, mainly incorporated into deoxyribonucleic acid.

When the culture medium has contained thymidine for 2 hr., a few nuclei, but no mitotic figures, are notably labelled. This number increases with time and, after long contact, all mitotic figures and most intercinetic nuclei are seen to contain tritium-labelled thymidine. But a variable number of nuclei (up to 30 per cent), mainly in the inner part of the growth zone, are free of silver grains even after three days of cultivation in the presence of the nucleoside. As they are intermingled with labelled cells, the possibility that they are too far from the film for the tritium electrons to reach it can be ruled out. It can thus be assumed that up to that number of cells do not participate in the mitotic cycle and that no turnover of deoxyribonucleic acid occurs in such cells. Auto-absorption, however, is an important factor, because there are more silver grains over large flattened nuclei than over small round ones. The ratio between nuclear area and number of grains can be analysed.

The ratio of labelled to the total number of mitotic figures has been determined after exposure to thymidine in the cultures for various lengths of time. The results are shown in Fig. 2. They make it clear that the stage of synthesis of deoxyribonucleic acid, involving nuclear incorporation of thymidine in insoluble compounds, occurs mainly between the sixth and eleventh hours before onset of mitosis in chick fibroblasts *in vitro* at 37° C. Independent evidence based on quantitative Feulgen determinations shows that synthesis of deoxyribonucleic acid precedes mitosis in the same material by 7–8 hr. on an average[5]; thus, there is near coincidence between fixation of this nucleoside and polymerization to deoxyribonucleic acid.

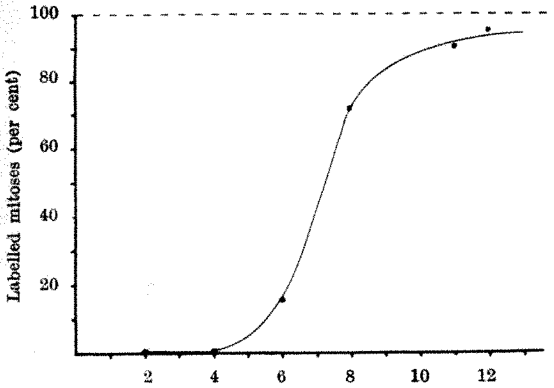

Fig. 2. Time relationship between thymidine labelling and mitosis

Counting the grains gives a fair estimate of the relative amount of thymidine present in structures of comparable thicknesses, such as the two chromosome groups of anaphases and telophases. The two always contain about the same number of grains. Deviation from equality in the two groups never exceeds what one would expect in a purely random process such as radioactivity. This is in accordance with the theory of equal division of deoxyribonucleic acid between the two daughter cells at mitosis, but not with the recent contrary findings of Plaut and Mazia[6] working on plant cells and using thymidine labelled with carbon-14 and consequently obtaining less accurate localization of the electron-emitting structure.

From these observations and others, to be published in detail elsewhere[5], it appears that tritium-labelled thymidine is a very useful tool for the cytological study of many aspects of the synthesis of deoxyribonucleic acid.

Reduction of Low-Temperature Injury to Stored Apples by Modulation of Environmental Conditions

INVESTIGATION of the metabolism of the senescent apple fruit has largely been directed to the practical objective of improving storage technique. Observations have generally been made on fruit kept in a constant environment. There is, however, no inherent reason why an environment favourable at one stage of post-harvest life should be equally favourable when applied at another stage. A. J. M. Smith[1] reported experiments that led to the adoption of a 'dual temperature' method in the refrigerated carriage of South African plums to the United Kingdom. I have already reported that with Victoria plums a change of temperature to 18° C. for two days on the seventeenth day after the commencement of storage at 0° C. resulted in a considerable delay in the subsequent appearance of the low-temperature injury described as 'internal browning'[2].

A similar result has now been obtained with the apple fruit (variety, Bramley's Seedling), although the magnitude of the effect is less than with the plum. In Fig. 1 the amount of low-temperature injury, measured as the estimated percentage surface discoloured brown in 50 apples cut in half transversely to the stem-calyx axis, is plotted against a time-scale representing the period elapsing between the commencement of storage and the application of a warming treatment. The treatment consisted of raising the temperature of the fruit to 15° C. for 5 days after which it was returned to its original storage temperature of 0° C. All the apples were cut at the same date, 18 weeks after the commencement of storage. It will be seen that as the date of the treatment was advanced there was at first a progressive reduction in the extent and intensity of injury but that this was followed by a regular increase. The amount of injury when no warming treatment was given was comparable to that in samples which were warmed at the end of the experiment, five days before examination. The minimum injury occurred where warming was applied in the period 6–8 weeks after commencement of storage.

This picture was changed in a striking way when during the warming treatment the fruit was exposed to a current of carbon dioxide and air (Fig. 2). The amount of injury found after 18 weeks of storage was greatly reduced, the degree of reduction being greater when the concentration of carbon dioxide during warming was 20 per cent than when it was 10 per cent.

I have already suggested that the hypothesis put forward by Plank[3] that low-temperature injury may be due to the toxic effect of accumulating volatile metabolites is consistent with the effect of warming observed with plums[4].

Fidler[5] has shown that when carbon dioxide was allowed to accumulate to a concentration of 8 per cent during storage at 3° C. the output of total volatile substances from the apple was reduced. It would be interesting to see if temporary warming in an atmosphere containing carbon dioxide as described here can be shown to have an effect upon the production of total volatile substances. Work to this end is now proceeding.

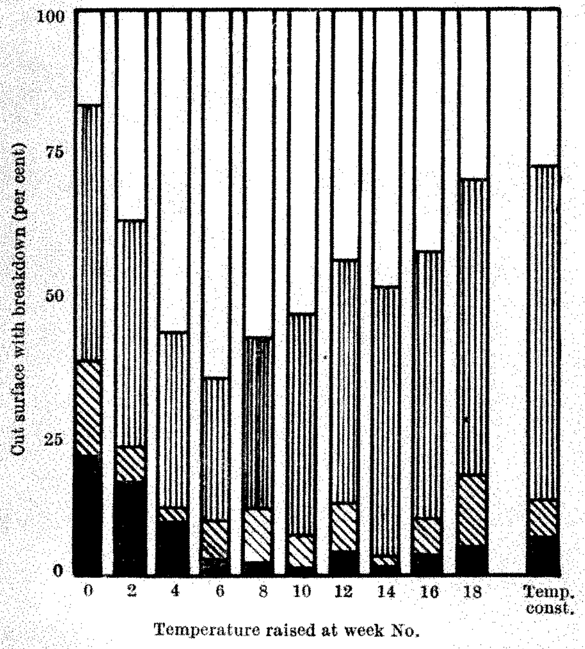

Fig. 1. Effect on occurrence of low-temperature breakdown of raising the temperature of apples (var. Bramley's Seedling) to 15° C. for five days at progressive intervals during storage at 0° C. (White, sound; vertical hatching, slight; oblique hatching, moderate; black, severe)

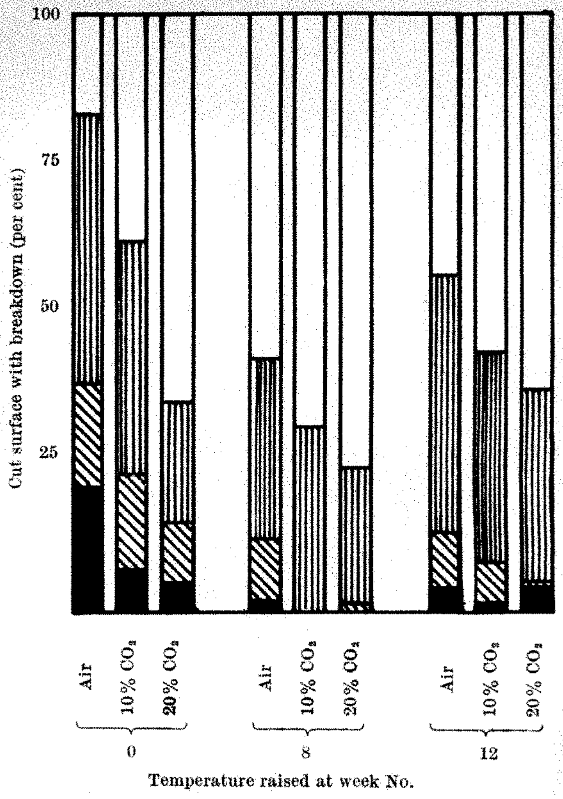

Fig. 2. Effect on occurrence of low-temperature breakdown of increasing the carbon dioxide content of the air in which apples (var. Bramley's Seedling) were kept for five days at 15° C. (White, sound; vertical hatching, slight; oblique hatching moderate; black, severe)

A Staining Technique for detecting Ratoon Stunting Disease in Sugar Cane

Ratoon stunting, a virus disease of sugar cane, is difficult to diagnose since the macroscopic symptoms are ill defined. Several tests described for diagnosing virus diseases in plants, including one for sugar cane[1], were tried but gave inconsistent results. Attempts were therefore made to develop a colour reaction for detecting the presence of the virus. The investigations were prompted by reports on the use of 2,3,5-triphenyl tetrazolium chloride to detect viruses in plants[2] and on the use of the same substance to localize the site of reducing activity in sugar cane[3].

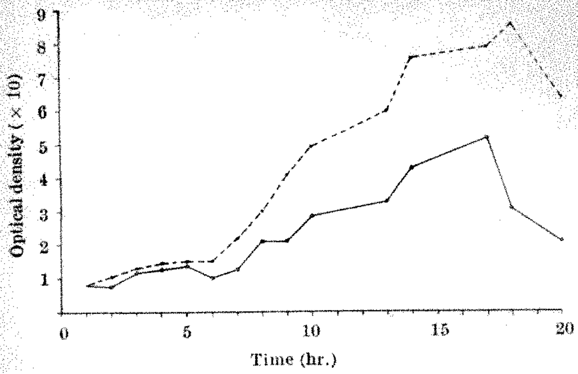

Fig. 1. Optical density of acetone extract. **Full** line, healthy; broken line, diseased

The test is based on the reduction of the soluble, colourless tetrazolium salt into the insoluble red formazan in the presence of viable tissues. It should be pointed out that little is known about the reducing mechanisms in the tetrazolium reaction. Furthermore, attention has been directed[4,5] to the photochemical properties of tetrazolium, a factor which demands carefully controlled conditions in experimentation.

The experimental procedure was as follows. Samples of cane tissue were taken from nodes of sugar-cane stalks by means of a cork borer cutting a plug 1 cm. in diameter. After sectioning the stalk at the level of the leaf scar, the plug was removed by boring vertically down into the lower internode, just inside the rind and opposite the bud. Slices, 0·5 mm. thick, were prepared by means of a hand microtome and the six sections immediately above the level of the leaf-trace bundles were selected. These were placed in 0·5 per cent solution of 2,3,5-triphenyl tetrazolium chloride and kept in an incubator, in darkness, at 35° C. The insoluble red formazan was extracted twice from the sections using each time 5 ml. of hot acetone. The optical density of the solution was determined by means of a Lumetron colorimeter, standardized with distilled water.

The change in colour was found to be more rapid with virus-infected than with corresponding virus-free tissue. The basal nodes of mature sugar cane stalks gave the best difference in colour intensity between healthy and diseased cane. Maximum difference was obtained when the four consecutive nodes above ground-level were sampled. When young canes were tested they reacted in the same way as young portions of mature cane, that is, colour development proceeded almost at the same speed in healthy and diseased tissue. Leaf punches taken from the mid-ribs also proved unsuitable for the test. Colour development being more rapid when the reaction is carried out in light, colour differentiation is better when the test is performed in darkness.

Cane tissue, when sampled in the internode, gave a minimum to no reaction. When sections were taken at the level of the leaf-trace bundles, reaction was too rapid in both infected and healthy tissue, and the large number of vascular bundles interfered with the development of a good colour pattern. The best zone for sampling was found to be just above the leaf-trace bundles, where the intermediate reaction gave a maximum difference in change in colour between healthy and diseased tissue.

The following sampling procedure was finally adopted. Six slices were obtained above the level of the leaf-trace bundles of the second and third nodes above ground-level. The twelve sections obtained were tested together for each stalk. The reaction was allowed to proceed for different lengths of time and the extraction carried out at intervals. The results are expressed graphically in Fig. 1. Although a difference in colour can be observed after 2 hr. when the reaction takes place in darkness, the best difference is obtained after, approximately, 9 hr. and is still very marked after 20 hr. It will be noted that there is a drop in both curves after seventeen to eighteen hours. It has been observed that the red colour fades and eventually disappears in the slices when left in the reagent, as well as in the acetone extract. It is therefore important to carry out the test under carefully controlled conditions.

More than 1,000 nodes were sampled from presumed healthy and diseased *M*.134/32 and *D*.109 canes growing in ratoon stunting field trials. Disease assessment by means of the colour test and macroscopic nodal symptoms[6] were in close agreement.

The method has its limitations in that it is applicable only to mature cane, and several varieties still have to be tested. The results obtained can be of only preliminary nature, and a more exhaustive study is being conducted.

Other tetrazolium salts, namely 3,3-dianisole-*bis*-4,4-(3,5-diphenyl)-tetrazolium chloride and 2-(*p*-iodophenyl)-3-(*p*-nitrophenyl)-5-phenyl tetrazolium chloride, were tested but did not show promise as colour indicators.

Occurrence of a Blue-Green Alga in the Nodules of *Trifolium alexandrinum*

DURING a cytochemical study of nodule cells in Egyptian clover, *Trifolium alexandrinum*, it was observed that in addition to the rhizobial bacteria, a blue-green alga, identified as *Nostoc punctiforme*, occurred inside the nodules. So far as we are aware, blue-green algae have not been reported to be associated with nodule formation in legumes.

The alga, at first, occupies the intercellular spaces in the nodules (Fig. 1, 2) and gradually invades the cellular region, forming globose to subglobose colonies (Fig. 1, 1). The trichomes are few-celled, though many occur as individual cells. The characteristic blue-green pigment, double-walled akinetes, intercalary heterocysts and yellowish-brown coloration with iodine help to distinguish the alga from the associated bacteria (Fig. 1, 3). The alga could be successfully cultured in sterilized Erdschreiber soil solution. The alga occurs only in the nodules of *T. alexandrinum*, the other parts of the plant showing no such organism.

Nodules of both diploid and tetraploid *T. alexandrinum* showed the alga, as well as those of *T. alexandrinum* collected from different localities. The alga was, however, absent in the nodules of *T.*

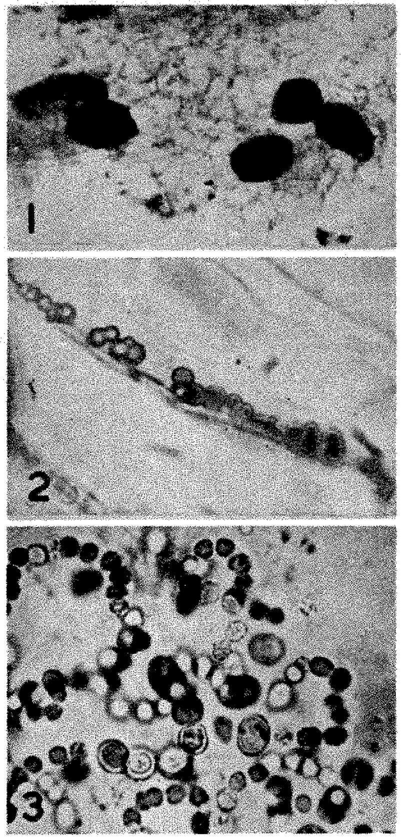

Fig. 1. (1) Colony of *Nostoc punctiforme* inside the root nodule. (2) Individual cells of the alga in the intercellular space inside the nodule. (3) *Nostoc punctiforme*, from culture, showing akinetes and heterocyst

pratense, *T. hybridum*, *Lupinus alba* and *Melilotus alba*, which were growing in the same fields as *T. alexandrinum* or in adjoining areas.

In some lower plants, blue-green algae, particularly those belonging to the genera *Nostoc* and *Anabaena*, have been reported to occur endophytically[1]. The occurrence of *N. punctiforme* in root nodules alone suggests that the relationship may not be a simple case of endophytism. Many blue-green algae are known to fix atmospheric nitrogen[2-4], and it is possible that *N. punctiforme* plays some such part. The reasons for the specific affinity of the alga to *T. alexandrinum* are also not clear. This legume is widely cultivated as a winter fodder in north India under irrigated conditions, and we are now studying the precise relationship between the alga and the leguminous nodule as well as the nitrogen-fixing ability of the alga.

We are indebted to Dr. M. S. Randhawa, Dr. B. P. Pal and Dr. S. M. Sikka for their interest in the study and encouragement. We are also grateful to Dr. M. S. Swaminathan for advice.

Agar Double Diffusion Precipitation Reaction applied to the Study of *Asterococcus mycoides*

The agar double diffusion precipitation reaction has been found of value in this laboratory in research on the organism of contagious bovine pleuropneumonia, *Asterococcus mycoides*. Two techniques are used, a modification of Ouchterlony's[1] method described by Mansi[2] and a method described by Jennings and Malone[3]. The reactions observed, and the interpretation of the results obtained, with the bovine pleuropneumonia organism have been essentially similar to those described by these authors. Jennings and Malone's method has the advantage that a positive reaction can be seen in 2 hr., and that more distinct separation of lines of precipitation occurs as diffusion proceeds; but larger quantities of serum and antigen are required than for the method of Mansi.

Immune sera are produced in rabbits by intravenous injections of increasing doses of washed organisms grown in a culture medium containing no bovine antigens[4]. No reaction is produced between normal rabbit serum and infected bovine tissues or extracts of the organism, or between immune rabbit serum and normal bovine tissues. When immune serum is tested against material from infected tissues, such as pleural exudate or a saline extract of a lung lesion, a strong reaction is seen. Usually three lines of precipitation are apparent, demonstrating that the organism contains at least three soluble antigens. Cultures and extracts of the organism also give the same result. All strains of the organism studied here have produced the three lines, indicating no qualitative difference in the antigenic structure of different strains.

Most areas in tropical Africa where contagious bovine pleuropneumonia is enzootic are relatively isolated, and communications with laboratories are therefore often slow and unsatisfactory. In these circumstances a laboratory diagnosis on specimens obtained post-mortem is usually difficult or impossible through lack of suitable fresh material from the field, and reliance must be placed on serological tests of other animals in the affected herd. Consequently a technique which enables a suspected diagnosis of pleuropneumonia to be confirmed at the laboratory by the examination of preserved, or of partially decomposed and contaminated, material would be most useful. In order to investigate the value of the precipitation reaction in these conditions, two samples of unpreserved contaminated material from bovine lung lesions were kept at room temperature and tested at intervals. The reaction remained positive for up to 13 days, by which time the specimens were completely putrified. Cultural examination of the two samples in a suitable medium, containing thallium acetate and penicillin to suppress other bacteria, failed on and after the second and third days respectively, due to gross contamination. It has been found that 5 per cent formalin and 50 per cent glycerin do not destroy the antigen, and the test can be satisfactorily carried out on infected tissues preserved with these reagents.

The sera of cattle dying of infection with *Asterococcus mycoides*, when tested against immune rabbit sera, often give one or two lines of precipitation, demonstrating the presence of circulating antigens, probably absorbed from the extensive lesions and exudate which always contain a high concentration of diffusible antigens.

It is intended to use this method in investigating the antigenic composition of the organism of bovine pleuropneumonia, and its relationship to that of caprine pleuropneumonia and possibly other pleuropneumonia-like organisms.

Incompatibility in *Theobroma cacao*

Knight and Rogers[1] postulated the existence of five incompatibility alleles, at a single locus, in the three self-incompatible but cross-compatible cacao genotypes studied by them. The five alleles differed in dominance, but two were equal; the same dominance sequence, $S_1 > S_2 = S_3 > S_4 > S_5$, was exhibited in both male and female parts of the flower. Their criterion of compatibility and incompatibility was the retention or fall, respectively, of hand-pollinated flowers guarded from insect visits.

I have used a different approach to the problem. Microtomed sections of pollinated ovaries have been microscopically examined. In all cases of self- and cross-incompatibility, a proportion of fertilized ovules shows non-fusion between the egg nucleus and first male gamete and between the polar nuclei and second male gamete; the remaining ovules show normal fusion. Three main types of self-incompatible tree are now recognized wherein the proportion of 'non-fusion' ovules is: (1) 25 per cent; (2) 50 per cent; (3) close to or actually 100 per cent. Compatible pollinations, on the other hand, give all normal ovules. *Theobroma cacao* L. provides, for the first time, an example of an incompatibility mechanism in the flowering plants which has non-fusion of gametes as its fundamental manifestation, the ratios of ovules wherein non-fusion and fusion of gametes take place bearing simple genetic ratios one to the other (1 : 3, 1 : 1, 1 : 0).

On a visit to the West African Cacao Research Institute in 1956, I was privileged to use some of the trees investigated by Knight and Rogers. Pollinated ovaries from guarded flowers were fixed, sectioned and examined.

All genotypes representing a combination of an allele and another recessive to it (for example, $S_{1\cdot 2}$, $S_{2\cdot 5}$, $S_{3\cdot 4}$) gave, on self-pollination, counts wherein the proportion of non-fusion ovules was 25 per cent. The $S_{2\cdot 3}$ genotype, a combination of alleles of equal dominance, gave 50 per cent non-fusion ovules on self-pollination. The $S_{5\cdot 5}$ genotype did not, however, give on selfing the expected 100 per cent non-fusion content; instead, it gave good 25 per cent counts, suggesting that, in fact, it is not homozygous, but is a combination of S_5 with a second allele recessive to it (say, S_6). The consequences of this assumption do not in any way invalidate the findings of Knight and Rogers.

Table 1. Percentage Ratios of 'Non-fusion' to Normal Ovules in Cacao Selfings and Crosses. Incompatible Combinations in Bold-face Type

Female	Male				
	$S_{1\cdot 2}$	$S_{2\cdot 3}$	$S_{2\cdot 5}$	$S_{3\cdot 4}$	$S_{5\cdot 6}$
$S_{1\cdot 2}$	**25**	0	0	0	0
$S_{2\cdot 3}$	0	**50**	**25**	**25**	0
$S_{2\cdot 5}$	0	**25**	**25**	0	0
$S_{3\cdot 4}$	0	**25**	0	**25**	0
$S_{5\cdot 6}$	0	0	0	0	**25**

Cross-pollinations between genotypes carrying the same dominant allele (for example, $S_{2\cdot 3} \times S_{2\cdot 5}$) also gave 25 per cent non-fusion ovules in the ovary. The cross, $S_{2\cdot 3} \times S_{3\cdot 4}$, found by Knight and Rogers to be incompatible, likewise gave 25 per cent non-fusion ovules.

All combinations that do not involve the same dominant allele (for example, $S_{1\cdot 2} \times S_{2\cdot 5}$, $S_{1\cdot 2} \times S_{3\cdot 4}$) and those that do not involve a duplication of alleles of equal dominance in the presence of the other (for example, $S_{2\cdot 5} \times S_{3\cdot 4}$) were found to give only normal ovules in the pollinated ovaries. Knight and Rogers found these combinations to be compatible.

The results are summarized in Table 1, which shows the percentage proportion of non-fusion ovules counted. The principal conclusions to be drawn from the results are: (1) that gametes carrying the same dominant allele are those that do not fuse in the embryo-sac; (2) that the fusion or non-fusion behaviour of gametes is determined by the S allele they carry interacting with the diploid tissues (for example, S_2 gametes fuse in $S_{1\cdot 2}$ tissues, but not in $S_{2\cdot 5}$ tissues), so that incompatibility or compatibility is ultimately determined by the diploid genotype and hence is sporophytically controlled; (3) the similarity of reciprocal pollinations.

From my observations on the incidence of compatibility and incompatibility in progenies arising from crosses between self-compatible and self-incompatible parents, the hypothesis put forward by Knight and Rogers, based on the operation of an allelic series at a single locus, appears inadequate. It seems necessary to postulate the existence of two independent loci, one (P,p) concerned with the production of an 'incompatibility precursor', and another (S), which imparts specificity to the precursor. The P,p locus shows simple dominance and recessivity, and acts before meiosis; the S locus shows allelomorphism and acts after meiosis. If either locus is inactive (pp and $S_{f.f}$, where the f indicates the presence of an amorph), full self-compatibility results. There will therefore be three main types of self-compatible tree: (1) $pp\ S_{a.b}$ (self-compatible by virtue of the non-production of the precursor); (2) $PP\ S_{f.f}$ (self-compatible by virtue of amorphism at the S locus); (3) $pp\ S_{f.f}$ (both loci inoperative). A cross between the first, believed to be representative of the Central-American self-compatible tree, and the second, thought to represent the Trinidad self-compatible, will produce offspring with both loci active, and hence all will be self-incompatible. This result has been obtained.

A Chromatographic Method for studying Simple Compounds in Plants

MOST chromatographic methods of investigating simple compounds (for example, saccharides and amino-acids) and their distribution in plant tissues have involved preparing extracts either of the whole plant or of dissected portions.

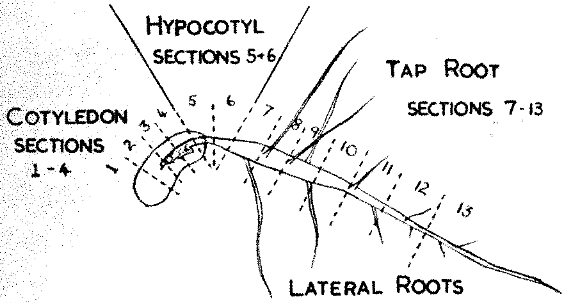

Fig. 1. Sectioned bean

I would like to indicate the possibilities of a less-elaborate technique to attain similar or more defined results. The method, comparable in principle to that of La Cour and Drew[1], is essentially to press the sap juices of the plant in question directly on to the chromatogram; instead of preparing water or alcohol extracts, concentrating and placing these on the chromatogram.

The plant studied in the initial experiments was a 14-days old seedling of the French bean *Phaseolus vulgaris*, var. Improved Canadian Wonder. This plant provided large amounts of sap, but other experiments with more woody plants also gave satisfactory results.

The beans were germinated for 14 days and then used immediately or stored at −20° C. until required.

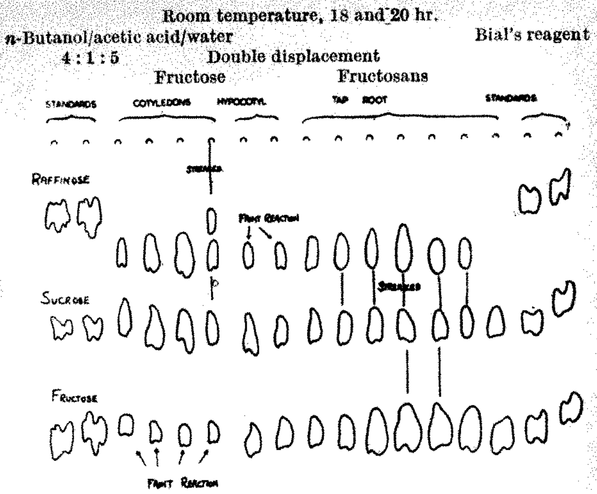

Fig. 3

(Stored beans were allowed to regain room temperature slowly before use.) The testa of the bean was removed and the plant divided into sections as shown in Fig. 1.

Each section was then placed at a marked position on the starting line of a paper chromatogram (Whatman No. 4, 22 in. × 18 in.), and its sap expressed by hand pressure exerted on a glass plate (4 in. × 6 in.) on top of the section. Underneath the chromatogram was another glass plate to prevent liquid loss and damage to the paper. When the sap had been absorbed by the paper and had spread to the desired spot size (¼ in. diam.), it was rapidly dried in a stream of hot air (30 sec.–1 min.). The process was repeated until most of the sap was removed from the section leaving only the skeleton of the section, which was discarded.

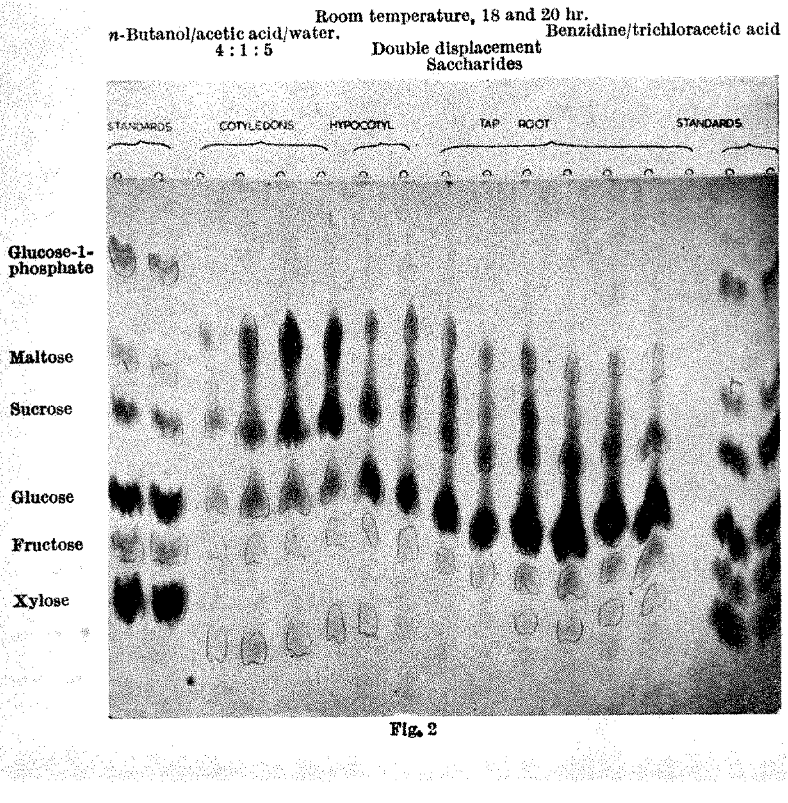

Fig. 2

Descending chromatography was then carried out using conventional techniques for the compounds under investigation.

By use of the appropriate series of sections, the sap components of a whole bean could be assembled on the paper in such a way as to indicate their distribution in the bean (Fig. 2). No detailed report on the findings will be attempted here; but, in summary, the results of the initial experiments showed that: (*a*) the method was applicable to such compounds as saccharides, including fructose and fructosans (Figs. 2 and 3), amino-acids and ultra-violet-absorbing substances; (*b*) there was an unequal distribution of these simple compounds between the cotyledons and the tap root. For example, fructose was found in the tap root but little was found in the cotyledons (Fig. 3). Proline was found in the cotyledons but not in the tap root, where a ninhydrin-reacting compound appeared to run to the same position; (*c*) the hypocotyl contained the smallest number of compounds.

This method may thus be of use in studying the distribution of simple compounds in the sap of whole or portioned plants during germination, and its application may also provide some information on translocation and other allied problems.

An objection to this method could be that the enzymes released by crushing are active in the time it takes to dry the sap and at the elevated temperatures of drying: this would complicate the picture observed. However, the sap is dried in a very short time, especially if an efficient hot-air dryer is used (30 sec. for the root section and 1–1½ min. for the cotyledon sections), thus minimizing enzyme action. In later experiments the area on which the sap was to be placed was impregnated with 5 µl. of a 0·01 *M* mercuric chloride solution[2] as an enzyme inhibitor and results were similar to those with spots submitted solely to heat treatment. It seems evident that enzyme action is so slight as to be negligible.

Fluorescent Substances produced by Dermatophytes

The fluorescent substances formed by *Microsporum* species and *Trichophyton schoenleini* when attacking hair *in vivo* have not been identified; recently Wolf[1], on the basis of *in vitro* studies of the growth of *M. canis* and *M. gypseum* on hair, has produced evidence indicating that one of the substances is a pteridine. It is felt that this conclusion should be accepted with reserve for the following reasons.

(1) Wolf has produced no evidence to eliminate the possibility that the fluorescent products obtained could not also have been prepared from uninfected hair; Chattaway and Barlow[2] have shown that fluorescent materials can be extracted by water from normal hair, but that these have different chromatographic and electrophoretic properties from those formed during fungal attack *in vivo*.

(2) No comparison was made with fluorescent materials extracted from naturally infected hair. It is well known (for example, Vanbreuseghem[3]) that the mode of attack of hair *in vitro* by these fungi differs markedly from that seen *in vivo*. The metabolism of the organism is likely, therefore, also to differ, and any fluorescent products obtained during *in vitro* growth cannot be assumed to be identical with those formed *in vivo* unless direct comparison of properties is made.

(3) Chattaway and Barlow showed that aqueous extraction of hair damaged by fungi removed a complex mixture of substances, and treatment of such an extract with charcoal and methanol as described by Wolf would almost certainly not effect any great purification of the fluorescent material. Since the evidence for the material being a pteridine rests on absorption spectra data, any correlation of such data with fluorescent substances is at least very uncertain without further purification of the materials.

(4) Chemical examination by Davidson and Gregory[4] of aqueous extracts from naturally infected hair showed the presence of nitrogen, an aldehyde group and a phenolic ring; while Robinson, Figge and Bereston[5] concluded from infra-red analyses that the fluorescent material was a peptide. Chattaway and Barlow confirmed the findings of Davidson and Gregory but showed that the phenolic substance could be separated from the fluorescent substances by chromatography and that the fluorescence was quenched by bromine water. It is difficult to interpret these findings as supporting the presence of a pteridine.

Streptomycin and Bacterial Respiration

There are many reports in the literature of effects of streptomycin on bacterial respiration[1]. Most of these involved the addition of streptomycin to non-growing suspensions of bacteria; but it seems likely that changes occurring during growth in the presence of streptomycin might ultimately prove of greater significance.

In the experiments described here, the effects on respiration of *Staphylococcus aureus* produced by exposure to dihydrostreptomycin during growth have been investigated.

Each experiment was performed as follows. Meat digest broth (50 ml. in a 250-ml. Erlenmeyer flask) was inoculated with *Staph. aureus* from an 18-hr. shaken culture in the same medium, to give a just-visible opacity, and the inoculated medium was incubated with continuous shaking for 2 hr. The density was then estimated absorptiometrically, and the culture was divided into two 25-ml. portions in 250-ml. flasks. The cultures at this stage contained staphylococci equivalent to about 1 mgm. dry wt. per ml. To one of these, dihydrostreptomycin in the required concentration was added (3 µgm.–50 µgm./ml.), and incubation of the flasks was continued, with shaking, for a further 2 hr. The cells were then harvested and washed three times with distilled water, by centrifugation. Suspensions were made in 0·1 *M* phosphate buffer, *p*H 7·3, and oxygen uptake with and without added substrate was measured for 30 min. by the conventional Warburg technique, no further dihydrostreptomycin being added at this stage. The dry weight of cells in the manometric experiments was 5 mgm./flask.

With succinate as substrate, the rate of oxygen uptake by cells which had been exposed to dihydrostreptomycin during growth was strikingly lower than that of the control cells. The decrease of oxygen uptake with glucose was, however, less marked and did not vary much with alteration of concentration of dihydrostreptomycin during growth. All figures are corrected for endogenous oxygen uptake of the respective cells, and are given to nearest 5 per cent.

Further experiments have shown that, under similar conditions, rate of uptake of oxygen with pyruvate is less affected than rate with succinate. For example, after exposure to 25 µgm. dihydro-

Table 1

No. of exp.	Oxygen uptake, dihydrostreptomycin-exposed cells with succinate (Control=100)	Oxygen uptake, dihydrostreptomycin-exposed cells with glucose (Control=100)	Di-hydrostreptomycin concentration during growth. (μgm./ml.)	Total growth of dihydrostreptomycin-exposed cultures on dry-weight basis (Control=100)
1	10	80	50	35
2	15	85	25	35
3	30	85	12	65
4	40	80	6	85
5	60	80	3	90

streptomycin/ml. during growth, rate of oxygen uptake with succinate was decreased by 85 per cent whereas with pyruvate the decrease was 20 per cent.

The effects described have not been called 'inhibition' of oxygen uptake, since it is possible that the underlying mechanism might be an altered balance of enzymes in the cells, due to differential effects of streptomycin on enzyme synthesis, and not a direct interference with oxidative enzymes already present. If the organisms are harvested less than 2 hr. after addition of dihydrostreptomycin, lesser degrees of reduction of oxygen uptake are found. With 25 μgm. dihydrostreptomycin/ml. present during growth, for example, the growth-curves of the dihydrostreptomycin and control cultures differ only slightly in the first ½ hr. of incubation, but thereafter diverge rapidly. The effects on oxygen uptake with succinate follow roughly the same pattern.

It is interesting to note that the streptomycin antagonist (2-heptyl-4-hydroxyquinoline-N-oxide) investigated by Lightbown and Jackson[2] strongly inhibits the oxidation of succinate if added to non-growing suspensions of *Staph. aureus*, whereas dihydrostreptomycin itself produces no measurable inhibition with this organism under these conditions.

Thanks are due to Mr. R. W. Warner for technical assistance.

Inhibition of Blood Digestion in Mosquitoes by Cations, and Cation-Antibiotic Mixtures

DURING the course of some studies originally designed to evaluate the role of certain cations and anions in influencing the susceptibility of *Aedes aegypti* to infection with *Plasmodium gallinaceum*, it became apparent that the calcium fed to these mosquitoes was also consistently inhibiting digestion of the ingested blood meal in a fairly constant proportion of the mosquitoes. This report extends this observation somewhat, and deals with some preliminary experiments on the inhibitory effects of the cations calcium and magnesium, alone and in combination with the antibiotic oxytetracycline, on the process of blood digestion in the mosquito *A. aegypti*.

In these experiments, the salts, antibiotic, and salt and antibiotic mixtures were added in the appropriate concentrations to a 4 per cent sugar nutrient solution which is generally used in this laboratory as the maintenance diet for mosquitoes. The solutions were made available to the adult mosquitoes immediately after pupal emergence was completed, and the mosquitoes were then maintained on these solutions for the following 72 hr. At the end of this period the mosquitoes were allowed to gorge on normal chicks. Following the blood meal, the mosquitoes were allowed to continue to feed on the drug solutions until the experiments were terminated. Normally, in mosquitoes maintained at a constant laboratory temperature of 26·5° C. and a constant relative humidity of 75 per cent, as in this case, a blood meal will have been completely digested within 72 hr. At the end of this period the stomach will be entirely empty and contain no microscopically discernible trace of the blood meal. In these experiments, in order to emphasize the extent of inhibition of blood digestion, dissection of the mosquito and examination of the stomach was delayed until the fourth day following the blood meal. In those mosquitoes in which digestion has been inhibited the blood remains as a kind of darkened, amorphous mass, about one-third the size of the clot resulting from the original blood meal. Microscopically, intact red cells are no longer evident although the residue still retains the characteristic orange-reddish colour of hæmoglobin. Chemically, the residue gives a positive test for hæm by the benzidine reaction.

Table 1. THE EFFECT OF FEEDING CATIONS, AND CATION AND ANTIBIOTIC MIXTURES, ON BLOOD DIGESTION IN *Aedes aegypti*

Regimen	Mosquitoes containing blood residues	Total mosquitoes	Mosquitoes containing residues (per cent)
Sugar	0	160	0·0
0·002 *M* oxytetracycline	0	172	0·0
0·1 *M* calcium chloride	52	166	31·3
0·1 *M* calcium chloride + 0·002 *M* oxytetracycline	117	164	71·3
0·1 *M* magnesium chloride	2	162	1·2
0·1 *M* magnesium chloride + 0·002 *M* oxytetracycline	64	165	38·7

It is evident from the data presented in Table 1, which summarizes the results of several experiments, that calcium markedly inhibited digestion, since 31·3 per cent of the blood-fed mosquitoes still contained an undigested residue 96 hr. after the original feeding. At the same time, oxytetracycline alone had no apparent inhibitory effect, since none of the mosquitoes fed on that compound contained any discernible blood residues even when they were examined as early as 72 hr. after the blood meal. When it was fed to the mosquitoes in combination with calcium, however, oxytetracycline markedly increased the inhibitory effects of calcium and as a result the proportion of mosquitoes still containing considerable blood residues rose to 71·3 per cent of the total animals in the group. This potentiating effect of oxytetracycline was even more evident when it was fed in combination with magnesium. Thus, as shown in Table 1, magnesium alone had almost no inhibitory effect, but when it was fed together with oxytetracycline, 38·7 per cent of the mosquitoes contained undigested residues 96 hr. after the blood meal. It may be noted here that chloride, fed to the mosquitoes in 0·02 *M* concentrations of hydrochloric acid, either alone or with oxytetracycline, had no discernible effect.

It is of interest to note that when 0·058 *M* concentrations of the trisodium salt of ethylenediamine tetraacetic acid are added to the solutions of calcium and magnesium alone, or to the solutions of calcium and magnesium combined with oxytetracycline, so that these ions are in effect removed by the resulting chelation, their inhibitory effects are simultaneously eliminated and blood digestion proceeds normally. Thus, this fact lends further support to the assumption that these inhibitory effects are produced primarily by the cations, and that the antibiotic acts rather by potentiating and activating either the cations or the reaction between the cation and the particular enzyme system involved, in a manner not yet understood, but differing from the usual reaction between cation and antibiotic[1] in which the activity of the one or the other is either eliminated or inhibited. It has been observed, too, that those mosquitoes containing large, undigested residues nevertheless produce eggs in great numbers. Even though egg-laying is apparently delayed in such mosquitoes, as evidenced by the fact that unlike normal eggs these eggs become heavily pigmented while still in the body, the fact that eggs are produced in quantity indicates that there has been no interference with digestion or assimilation of the plasma fraction of the ingested blood meal, since it is well known that it is this fraction which the mosquito requires for egg laying. In view of this, and other data presented above, it appears reasonable to assume that only digestion of the hæmoglobin fraction, of all the fractions contained in the original blood meal, is affected by the cations, or cation and antibiotic mixtures.

Response of the Adrenal Medulla of the Sheep Fœtus to Asphyxia

OCCLUSION or ligation of the umbilical cord of the fœtal lamb is followed by a rise in arterial blood pressure and changes in heart-rate[1-5]. These reactions, which have been attributed to asphyxia, can be first elicited after 80–90 days of pregnancy and become more pronounced in the mature fœtus. The magnitude of the reactions has been related to the development and maturation of the autonomic nervous system[5].

In the present experiments the output of adrenaline and noradrenaline from the adrenal gland has been studied in fœtal lambs of different ages from 80 days of pregnancy until about term (150 ± days). The fœtus was removed from the uterus under pentobarbitone sodium anæsthesia, but the umbilical cord and the placental circulation were retained until the induction of asphyxia. Venous effluent blood was collected from the left adrenal gland after heparin (1,000 I.U./kgm.) had been injected into both the maternal and fœtal circulations. The left splanchnic nerve was cut and, when necessary, the peripheral end stimulated from an induction coil. Asphyxia was induced by ligation of the umbilical cord; a mask placed over the mouth of the fœtus prevented distension of the lungs or respiratory exchange. The adrenaline and noradrenaline content of the blood and of the adrenal glands was estimated by the method of Vogt[6].

The resting level of adrenaline and noradrenaline secretion from the denervated adrenal medulla is normally very low[6]; this was confirmed for the fœtal lamb. After ligation of the umbilical cord, large amounts of the sympathomimetic amines appeared in the fœtal adrenal effluent blood. Both adrenaline and noradrenaline were released, but noradrenaline was invariably predominant, irrespective of the age of the fœtus (Fig. 1, *a*). This discharge from the fœtal adrenal medulla continued until the fœtal heart stopped which, in the majority of experiments, was about 10–15 min. after ligation of the umbilical cord.

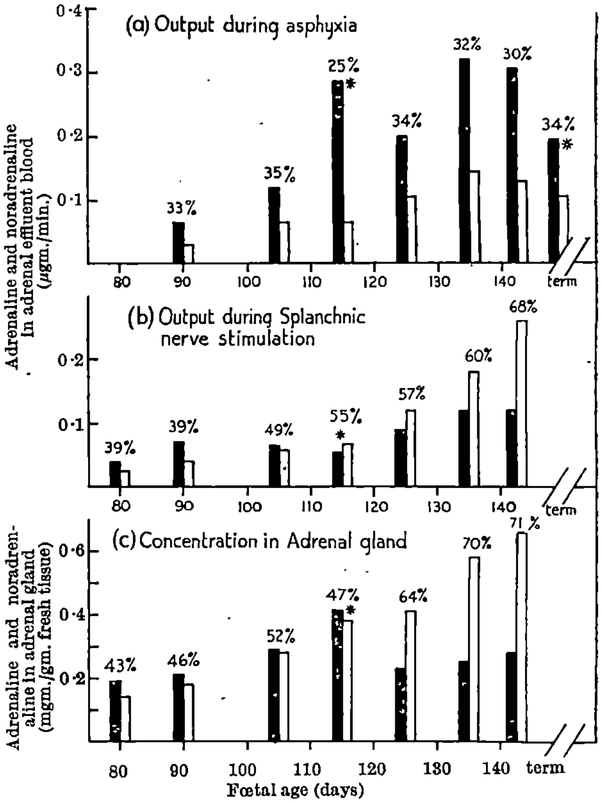

Fig. 1. Adrenaline and noradrenaline output and content of fœtal adrenal glands in the sheep. The percentage of adrenaline is given above each histogram. Black, noradrenaline; white, adrenaline. * One experiment: other figures are means of two or more experiments

The characteristically high concentration of noradrenaline in the fœtal adrenal blood during asphyxia is in marked contrast to the response obtained during stimulation of the left splanchnic nerve. With this stimulus the ratio of adrenaline to noradrenaline in the adrenal effluent blood corresponded to that in the gland. Thus when, in the last part of pregnancy, adrenaline became the major sympathomimetic amine in the adrenal gland of the fœtal lamb, it also became the dominant amine in the adrenal effluent blood during stimulation of the splanchnic nerve (Fig. 1, *b*, *c*).

The left splanchnic nerves were cut in the present experiments, and thus the response of the fœtal adrenal to asphyxia cannot be attributed to a reflex discharge similar to that reported in the adult[7,8]. Only a trace of sympathomimetic amines was detected in arterial blood samples taken after umbilical cord occlusion. It is therefore improbable that the right adrenal of the fœtus, which retained its splanchnic innervation, contributed to the high concentration of these amines in the effluent blood from the left gland. This sensitivity of the fœtal adrenal medulla to asphyxia may be particularly important in those species, such as the cat and dog[9,10] and the rabbit[11], in which the reflexes mediated by the autonomic nervous system are not as well developed at birth as those of the lamb.

Effect of Two Extreme Temperatures on Growth and Tail-length of Mice

EACH of six mouse litters (taken from mice that had spent their pregnancy period in the cold environment of 50° ± 5° F.) was divided into two nearly equal groups *A* and *B* at weaning time. Group *A* was kept in the original cold environment and the other group, *B*, was transferred to the hot environment of 92° ± 1° F.

At the age of 7 weeks, that is, after four weeks in the hot room, all mice were weighed and the length of tail was measured between the tip of the tail and the point where the hair on the body ends, that is, the naked more or less hairless tail which was completely exposed to the environmental conditions.

Table 1 shows the mean body-weights of mice at weaning time and at 49 days old.

Table 1

Mice	Sex	Mean weight (gm.)	Max.	Min.
At 21 days	Males (19)	7·33 ± 1·60		
	Females (21)	7·47 ± 1·40		
Group *A**	Males (8)	20·33	24	13
	Females (11)	20·54	24	14
Group *B*†	Males (10)	15·10	20	11
	Females (8)	14·40	19	10

* After seven weeks in the cold environment.
† Three weeks in the cold environment, followed by four weeks in the hot environment.

At 49 days, the mean lengths of tail were: Group *A* (20 mice), 6·75 ± 0·65 cm.; Group *B* (18 mice), 7·92 ± 0·55 cm.

The results obtained showed that mice when raised in a cold environment grew normally, but when the environment was changed from the cold to a hot one, this growth was retarded. With regard to the effect on length of tail, it is obvious that the high temperature caused an increase in the length of tail as compared with the cold environment although both groups of mice were brothers and sisters from the same litters. This appears to be a reaction for increasing or decreasing the body surface area to facilitate either heat loss or heat conservation respectively.

An Acid-fast Bacillus isolated from the Lungs of the Cape Hyrax, *Procavia capensis* (Pallas)

IN August 1954 a large epitheloid granuloma containing acid-fast bacilli was observed in a lung from Cape hyrax (locally known as 'dassie'). This particular animal had been received from New Bethesda, a small village in the north-eastern region of the Cape Province.

A further 86 'dassies' from the New Bethesda district were examined, and granulomatous lesions were found in the lungs of four animals. The infected animals all came from the same farm. Material from these lungs was injected intraperitoneally and subcutaneously into further 'dassies'. One of these animals developed a caseous inguinal lymph gland containing numerous acid-fast bacilli. This caseous material was planted on various culture media, and after four months one of us (G. B.) succeeded in isolating an acid-fast organism in pure culture on Dorset's egg medium.

Morphology and cultural characteristics. The isolated organism is a Gram-positive, acid-fast, non-motile, slender, straight or slightly curved rod, measuring approximately 1·5–2μ × 0·3–0·5μ. Much's granules are often observed. It is usually possible to differentiate microscopically the 'dassie bacillus' from the vole bacillus, particularly in artificial culture.

The organism grows slowly on ordinary mycobacterium media, although Dorset's egg medium is superior. The addition of 5 per cent glycerin does not benefit the organism. It grows better at 37° C. than at 26° C. Visible growth in primary culture usually occurs after 3–4 weeks incubation, whereas in subculture it may develop in approximately a week.

The colonies are of two types; one is small, round, raised, matt, regular, almost white; the other type is considerably larger, flat, irregular and with a raised centre. The differentiation is particularly marked after 2–3 months of incubation.

It survives without subculturing for at least a year. It is sensitive to streptomycin, rimifon and *p*-amino-salicylic acid.

Biological features. Saline suspensions of the culture were inoculated into 'dassies', rabbits, guinea pigs, white rats, white mice, and several varieties of veldt rodents. The lesions produced in these animals were very similar to those produced by the vole bacillus[1] (*Mycobacterium muris*, Wells, 1937). In view of this[2], series of *Mystromys albicandatus*, guinea pigs and white mice were inoculated with comparable doses of vole bacillus and 'dassie bacillus' respectively. The lesions, after intramuscular inoculation into *Mystromys* and guinea pigs, were of two types: local abscess formation and generalization. The lesions produced by the vole bacillus were far more severe than those produced by the 'dassie bacillus', but the animals invariably recovered. In white mice, however, the vole bacillus on intravenous inoculation produced a progressive fatal pneumonia. In contrast, those inoculated with 'dassie bacillus' developed an early generalized miliary infection which regressed. The animals still appeared healthy five months later.

In conclusion, the 'dassie' bacillus shares morphological, cultural and biological characteristics with the vole bacillus. Further studies are being undertaken to determine whether the 'dassie' bacillus should be classified as an almost non-virulent variant of the vole bacillus, or if it should be considered a new species.

Microbial Growth Stimulants in Spleen

Previous studies have revealed that rabbit spleen contains unidentified, water-soluble substances that are growth stimulatory for *Escherichia coli*[1], and also that beef spleen yields heat-resistant, water-soluble extractives stimulatory for species of pathogenic fungi[2]. A blood agar medium incorporating aqueous spleen infusion was formulated for the isolation of pathogenic fungi at 37° C. [2]. The stimulatory effects of spleen extracts on the growth of micro-organisms in chemically defined culture media has been investigated by us.

We have found that bovine spleen contains an active growth-factor which is highly stimulatory for the growth of a variety of micro-organisms when tested in several chemically defined culture media. Some of the species include the yeasts, *Candida albicans*, *Cryptococcus neoformans* and *Saccharomyces cerevisiae*; the protozoa, *Ochromonas malhamensis* and *Tetrahymena pyriformis*; and the bacterium, *Lactobacillus casei*. A preliminary purification procedure of the spleen factor was accomplished by following photometrically the turbidimetric growth response of a vitamin-depleted strain of *C. albicans* in a chemically defined liquid culture medium.

One kgm. of fresh, de-encapsulated and de-fatted beef spleen was thoroughly ground and mixed with 2 l. of distilled water. The resulting mixture was infused at 50° C. for 1 hr., occasionally agitated, and then rapidly heated to 80° C. for 5 min. in order to coagulate heat-precipitable proteins. The hot mixture was filtered through a layer each of towelling, gauze and cotton. The filtrate was cooled to 10° C. to congeal any remaining fat, which was removed by filtration through paper. The latter filtrate was autoclaved at 121° C. (15 lb.) for 15 min. in order to produce additional protein coagulation. Autoclaving did not reduce the growth-stimulatory effect of the spleen infusion for *C. albicans*. One litre of aqueous crude spleen extract, which had a *p*H of 6·8, was lyophilized and 23·5 gm. of a tan amorphous powder was obtained. This powder was extracted with one litre of anhydrous methanol at 20° C. for 15 min. The methanol-insoluble residue was microbiologically inactive for *C. albicans* and therefore was discarded. The amber-coloured, methanol filtrate which contained the active principle was mixed in a separatory funnel with an equal volume of pentane (Eastman technical) at 20° C. and shaken gently and intermittently for 10 min. An inactive, white flocculent precipitate which formed in the lower methanol layer was discarded together with the inactive pentane layer. The methanol fraction was reduced in volume in an all-glass distillation apparatus *in vacuo* at 60° C. and then dried over a steam bath until dark brown solids weighing 9·36 gm. were obtained. These were dissolved in double-distilled water and dialysed for 2, 8, 12 and 36 hr. at 5° C. through transparent, seamless, cellulose dialyser tubing (Thomas 4465 A_2) in a stationary water bath of double-distilled water. The four separate dialysates were combined, then concentrated *in vacuo* at 60° C. and lyophilized, yielding 6·66 gm. of light brown, hygroscopic solids. When these solids were assayed in a chemically defined liquid medium with a vitamin-depleted strain of *C. albicans*, they produced characteristic dose response growth-curves which showed an average half-maximal value of 35 μgm./ml.

The active growth-factor is soluble in water, methanol, ethanol and other alcohols, but is insoluble in diethyl ether, chloroform and pentane. In aqueous solution, the factor is unaffected by boiling, freezing or by autoclaving at 121° C., the latter in the presence or absence of dilute hydrochloric acid. Dry solids are stable for at least one year when maintained in a desiccator at 5° C. The spleen factor is also stable in methanol solutions. Studies embracing the further purification and characterization of the stimulatory substance, as well as its relationship to known water-soluble vitamins, are in progress. These will be described in later publications.

Amino-acid Composition of Sclero-protein of the Sponge *Hippospongia equina*

We have applied the method of paper partition chromatography to ascertain qualitatively the detailed amino-acid constitution of spongin, using the commercial unbleached honeycomb sponge, gathered in the eastern Mediterranean Sea. Our results differ in important respects from those of Low[1], who used this method to investigate the amino-acid constitution of the barium hydroxide hydrolysate of the sponge, *Spongia officinalis obliqua*, collected in the Gulf of Mexico.

We have examined both acid and alkaline hydrolysates of the sponge, previously washed with water and air dried. The acid hydrolysate was prepared by heating the sponge under reflux for 8 hr. with equal parts hydrochloric acid (6 *N*) and formic acid (85 per cent), while the alkaline hydrolysate was obtained by heating under reflux for 8 hr. with saturated barium hydroxide solution. The solvents and various location agents were all prepared according to Smith[2], while this author's dipping technique was also used. For final confirmation all the spots were extracted and run as one-way chromatograms against known standards.

The amino-acids identified in the acid and alkaline hydrolysates of spongin are given in Table 1. The relative intensity of the amino-acid spots is indicated by representing strong as + + + + and weak as +.

Tryptophan was confirmed with the Ehrlich reagent; tyrosine and histidine with the diazo reagent; iodinated tyrosines with ceric sulphate–

Table 1

	Alkaline hydrolysate	Acid hydrolysate	Relative intensity of amino-acid spot
Alanine	×	×	+++
γ-Aminobutyric acid	×		++
Arginine	×	×	+++
Aspartic acid	×	×	+++
Cystine	×		+
Glutamic acid	×	×	+++
Glycine	×	×	++
Histidine	×	×	++
Hydroxyproline	×	×	++++
Leucine–*iso*leucine	×	×	++++
Lysine	×		++
Ornithine	×		++
Phenylalanine	×	×	++++
Proline	×	×	++++
Serine	×		++
Threonine	×	×	++
Tryptophan	×		+
Tyrosine	×	×	++
3-Iodotyrosine		×	+
3 : 5-Diiodotyrosine	×		++
Valine	×	×	++

arsenious acid[3]. Two very faint spots which could not be identified appeared in the chromatograms of the acid hydrolysate after dipping in ninhydrin. Spot *A* was characterized by an R_F of 0·23 in butanol/acetic acid and 0·63 in phenol/ammonia: spot *B* gave values of 0·25 and 0·82 in the corresponding solvents. Spot *B* (see above) together with two other very faint spots *C* and *D* were also observed in chromatograms of the alkaline hydrolysate. Spot *C* had R_F values of 0·16 and 0·62 and spot *D* 0·35 and 0·73 respectively in butanol/acetic acid and phenol/ammonia.

All the amino-acids identified by earlier workers were confirmed except α-aminobutyric acid, dibromotyrosine and methionine found by Low[1]. No signs of these compounds could be detected, while oxidation of the valine spot with hydrogen peroxide failed to reveal any methionine. Contrary to Low's findings 3-iodotyrosine could not be detected in the alkaline hydrolysate, although it was identified in the acid hydrolysate. Considered together with the absence of 3 : 5-diiodotyrosine in the acid hydrolysate it is probable that the monoiodo-compound was present as an artefact.

We thank Mr. L. Nidditch, chairman, for laboratory facilities and the Brewing Industry Research Foundation for supplying quantities of ornithine and γ-aminobutyric acid.

Fluorescence of the Crystalline Lens and Electroretinographic Sensitivity Determinations

It is generally assumed that the human lens acts like a colour filter in front of the retina, reducing the sensitivity in the short wave-length region of the spectrum. In isolated lenses, absorption depends both on wave-length and on the age of the subject. Comparison of sensory spectral sensitivities of normal and aphakic (lensless) eyes has yielded information on the absorption of the lens *in vivo*[1]. We have obtained comparable information, using the electroretinogram as an index when untrained subjects are tested.

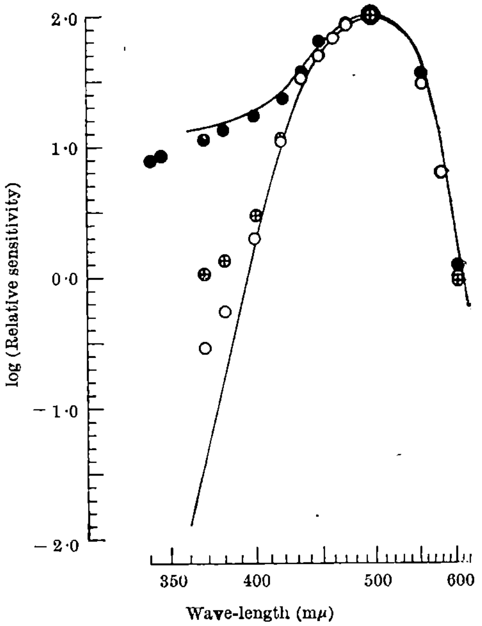

Fig. 1. Average spectral sensitivity of two aphakic eyes (filled circles), one normal eye, age 26 (open circles), and one normal eye, age 61 (crossed circles) as determined by measurement of energies producing scotopic *b*-waves of constant size (200 μV.). Spectrum of equal quantum intensity; values in terms of 497 mμ at 100 per cent. The curves represent spectral sensitivity of rod vision in an area 8° above the fovea in the normal (lower part) and aphakic (upper part) eye as determined psychophysically by Wald (ref. 1)

In order to lower the spectral limit from 400 to 341 mμ, a xenon high-pressure lamp and double-interference filters were used for stimulation. The filters were carefully selected to ensure both sufficient intensity and monochromasy (for details see ref. 2). A series of experiments was carried out on aphakic eyes of two subjects, 26 and 37 years old respectively, and on the normal eyes of two other subjects, 26 and 31 years old respectively. The average relative spectral sensitivities were calculated from the relative number of quanta eliciting *b*-waves of equal size, and their logarithms were plotted against wave-length; 497 mμ was chosen as reference standard. The results were compared with the curves for rod vision given by Wald[1] (Fig. 1).

As regards the visible part of the spectrum, there has been some discussion about the reason why sensitivity curves derived from measurements of scotopic *b*-waves are shifted towards the blue part of the spectrum[3]. Altogether, our electroretinographic determinations in the visible part of the spectrum from both normal and aphakic eyes, show rather close correspondence to Wald's curve. Peak spectral sensitivities were achieved at filter 497 mμ.

For the ultra-violet wave-length region, the values obtained from aphakic eyes fit the corresponding psychophysical curve fairly well. No differences were seen between the 26- and the 37-years-old subject respectively. However, for the young normal subject the ultra-violet sensitivity lies above Wald's curve. The corresponding values for the old normal eye are even higher. Since the absorption of the lens for short wave-lengths is known to increase with age[1,4], lower sensitivities would be expected in the older eye. When one observes a normal eye illuminated with ultra-violet light strong enough to cause a medium electroretinogram response, the lens appears as a whitish patch in a dark surround, that is, it fluoresces. The upper limit of the spectral region where fluorescence occurs lies at short wave-lengths in children and moves to longer wave-lengths with age[5]. It is tempting to relate these facts to the observed increase of spectral sensitivities, which also depends on age. Thus, fluorescence might account for the discrepancy between electroretinogram and sensory spectral sensitivity curves respectively.

This view is supported by further measurements relating response amplitude to stimulus intensity. The slopes of the curves for normal eyes are steeper in the ultra-violet than in the visible spectrum, thus showing why Wald's relative ultra-violet sensitivities for intact eyes are lower than those reported here. His values were obtained by absolute threshold determinations, whereas electroretinogram measurements require intensities much above the absolute threshold.

This work was supported by grants from the Deutsche Forschungsgemeinschaft towards the cost of apparatus. The support of this investigation by the Department of Ophthalmology, University of Heidelberg, which referred patients with lensless eyes to us, is gratefully acknowledged.

Effect of a Raised Peripheral Temperature upon the Rate of Regeneration in a Mammalian Peripheral Nerve

It has recently been reported[1] that an environmental temperature close to freezing point inhibited nerve regeneration in the rat's caudal nerve after crush injury. In these experiments only the peripheral part of the nerve was cooled, the temperature of the cell body being unaltered (for details, see Gamble and Jha[2]).

Similar experiments have now been made upon ten rats kept at room temperature (21–22° C.) and upon six kept in heated cages (35° C.). In these conditions the body temperatures are the same, but the subcutaneous temperatures in the tail differ. In the animals kept at 21–22° C. the subcutaneous temperature in the tail at a level close to the nerve injury was found to lie between 27° C. and 30° C. In the animals kept at 35° C., subcutaneous temperatures in the tail ranged between 32° C. and 36° C. It is likely, however, that during much of their sojourn in the heated cages subcutaneous temperatures of these animals lay between 35° C. and body temperature (36–39° C.).

Where the caudal temperature lay between 27° and 30° C. only equivocal evidence of remyelination was found when survival lasted 15–19 days after nerve crush (five animals). Many fibres showed double, wavy osmophilic lines, suggestive of cylinders of rather variable calibre, separated longitudinally by gaps of variable extent. It seemed reasonable to suppose that these cylinders represented very early stages in the process of remyelination. It was not until after 21 days survival, however, that unequivocal evidence of remyelination was obtained (three specimens). Nodes of Ranvier were distributed evenly along the majority of the fibres, the internodal lengths being short and uniform in all fibres. This condition was found after only 12 days (one specimen) and 14 days (three specimens) where the subcutaneous temperature lay close to 35° C.; evenly spaced nodes of Ranvier at short intervals again provided unequivocal evidence of remyelination in the majority of the fibres. After less than 12 days in the heated cages, only equivocal evidence of remyelination was found.

It is concluded that raising the temperature of the tissues through which regenerating axons pass by some 5–10° C. (from 27–30° C. to 35–37° C.) considerably speeds the earlier stages in the remyelination of those fibres. Other work in progress in this Department suggests that this effect is continued into later maturation stages.

The lower temperatures involved in these experiments lie well within the range found both subcutaneously and more deeply in the distal parts of the limbs of man. A proximodistal temperature gradient in the limbs might be related to Sunderland's[3] findings that, in the longer human nerves, regeneration after injury is more rapid in the proximal than in the distal parts. It seems possible, at least, that human nerve injuries might respond to heat treatment of a very simple kind by acceleration of the growth and maturation of regenerating fibres.

A Method for studying separately the Properties of the Innervated and Non-innervated Membrane of an isolated Single Electroplax of the Skate

The cellular unit of the electric organ of the skate (*Raja eglanteria*) is morphologically similar to that of *Electrophorus electricus*: both have rather large dimensions, although the electroplax of the skate is smaller and more irregular in shape; both have an innervated and a non-innervated membrane, the latter characterized by prominent digitations. There are, however, some differences of functional properties. The discharge of the organ in the intact animal has been studied by Albe-Fessard[1] and that of the individual electroplax by Brock *et al.*[2].

In view of the morphological similarity of the electroplax of the two species, it seemed worth while to try to adapt a new method recently developed for the single isolated electroplax of *Electrophorus* to the

niversity College Of

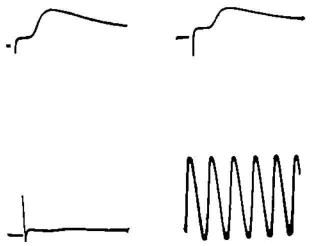

Fig. 1. Discharge of a single isolated electroplax from the skate (*Raja eglanteria*) before and after application of 0·1 μmole/ml. of *d*-tubocurarine chloride to the solution bathing the innervated membrane. From upper left to lower right: control; 1 and 4 min. after application of curare. Calibration: 5 msec., 100 mV.

corresponding unit of the skate[3–5]. This method consists in keeping a single isolated electroplax between a nylon sheet containing a window adaptable to the size and shape of the cell and a grid formed by nylon threads. The electroplax separates two pools of fluid, one of them bathing the innervated, the other the non-innervated face. Ion movements across the two types of membranes may be studied separately, and the electrical activity may be recorded with either extra- or intra-cellular electrodes. By-passing of ions has been excluded. Electrical activity remains unchanged for 6–8 hr. This method has now been adapted with minor modifications to the isolated single electroplax of the skate.

Fig. 1 shows the electrical activity recorded with extracellular electrodes and the effect of *d*-tubocurarine chloride (0·1 μmole/ml.) in the solution bathing the innervated site. The cell discharges in response to an electric stimulus with a latency period of about 3 msec. The amplitude of the response is about 30 mV. with a duration of 15–20 msec. Curare completely abolishes the response within 4 min.

The characteristics of the response are virtually the same as described by Brock *et al.*, thus confirming their finding. The advantage of the new preparation is the possibility to test the properties of the innervated membrane independently from those of the non-innervated membrane. Since it has been shown[5,6] that the two types of membranes of the electroplax of *Electrophorus* have different properties as to electric responsiveness, resting potential, ion movements and passive permeability, a study of the functionally different innervated membrane of the skate, now shown to be possible with the new method, is of obvious interest.

This work was supported in part by the Division of Research Grants and Fellowships of the National Institutes of Health, Grant No. *B*–400, United States Public Health Service, and by the Atomic Energy Commission, Contract No. *AT*(30–1)–1503.

Effect of Periodic Acid on Histochemical Aldehyde Blockades

SOME histochemical investigations still in progress required the use of an aldehyde blockade that would resist treatment with periodic acid and Schiff's reagent. Aldehyde groups were developed in sections of mouse tissues by oxidation with periodic acid reagent[1], by the Feulgen hydrolysis, or by carrying out these reactions successively on the same sections. Then, after blockading with hydroxylamine reagent[2], aniline hydrochloride[3], phenylhydrazine reagent[4], or 0·4 per cent w/v 1-dimethylcyclohexane-3 : 5 dione, the preparations were treated for 5 min. with the periodic acid reagent, which was followed by Schiff's reagent (E. Gurr, Ltd.) for 15 min.

Hydroxylamine blockade failed to resist treatment with periodic acid, and the sections stained with Schiff's reagent in the same manner as controls. By varying the time of initial treatment with periodic acid it was found that the staining of blockaded preparations could not be due to generation of additional aldehyde at sites where the initial oxidation might have been incomplete; hence, it seemed that periodic acid must be liberating aldehydes from aldoximes at the sites blockaded. Since there was no staining when 0·1 *N* hydrochloric acid was substituted for periodic acid after blockade, aldehyde liberation evidently was not due to acid hydrolysis alone. In some experiments with aldehydes developed by Feulgen hydrolysis, by treating sections with hydroxylamine and periodic acid alternately in series, the blockade could be broken down and reformed repeatedly.

Blockades with aniline and phenylhydrazine were resistant to periodic acid, except in the case of elastic membranes of blood vessels, which were stained strongly with Schiff's reagent. When 0·1 *N* hydrochloric acid was substituted for periodic acid after blockade, these membranes were stained just perceptibly. In all cases, this staining of elastica could be prevented by interposing a hydroxylamine blockade before Schiff's reagent.

1-Dimethylcyclohexane-3 : 5-dione did not block the reaction of aldehydes with Schiff's reagent at all sites; but where blockade was effective it was also resistant to periodic acid.

These results may be compared with those of Lillie[5], who found that 1 per cent periodic acid could liberate aldehydes at sites previously blocked with cyanide. However, his observation that blockades with aniline and phenylhydrazine were completely resistant to periodic acid apparently needs some qualification. Furthermore, it seems that when interpreting results of the periodic acid–Schiff reaction one must now envisage that some part of the staining may arise from the action of periodic acid on compounds having reactive groups analagous with the aldehyde condensation compounds that can be attacked by this reagent.

A Quantitative Study of Stasigenesis in Fissipede Carnivores

In the course of quantitative evolutionary studies on the dentition of fissipede carnivores we[1] have recently published a paper utilizing two angular measurements, α measuring the relation of protoconid height and talonid length in lower M_1 and β the relation between total length and protocone height in upper P_4. Graphic representation on Cartesian co-ordinates of the two values thus obtained for a number of species shows that the relative position of the values of α and β has an important biological significance, since it reveals the general phylogenetic tendencies of the group and its constituent sub-groups, and is in close agreement with the qualitative findings of taxonomy.

We are now continuing the work utilizing linear measurements. In the lower jaw of the Fissipedia we distinguish three regions of different functional significance. P includes the premolar series up to the paraconid of M_1; C measures the small sector from here to the protoconid of the same tooth; and T includes the remainder of the molar series. The different types of specialization found in fissipede carnivores are reflected in the very diverse magnitudes of these three regions, and when plotted reveal a pattern of points representing the species concerned. These are distributed around a central zone with a regularity capable of calculation. The parameters of the three regions, expressed in percentages, have been plotted with triangular co-ordinates in Fig. 1.

This graph reveals some striking similarities with that obtained from the values of α and β, and, at the same time, some notable differences. The variations in the values of P, C and T show that the amplitude is smaller for P. The radiation of fissipede carnivores from the time of its inception involved variations in the regions C and T. Only two families, the Ursidae and Hyaenidae, show specialization involving variation in the value of P.

Palæontological research has shown that these two families are of comparatively recent origin, and that they were not differentiated in the initial phase of carnivore evolution from a basal form such as *Cynodictis*, which is considered as an ideal ancestor of the group (synthetotype) because of its generalized condition and its central position in the graph.

Progressive differentiation in accordance with the idea of cosmolysis propounded by Blanc[2] results in the belated appearance of types capable of filling new ecological niches. ('Cosmolysis' is a term proposed by A. C. Blanc to denote the process of demixture and segregation of characters in an originally homogeneous population leading to the production of progressive heterogeneity and distinct groups, with particular reference to the origin of the different races of man ('anthropolysis'), on the analogy of magmatic differentiation in the inorganic world.) This is where variations in the value of P became possible. This new formation of families started in the Pliocene, the period that represented the climax of fissipede evolution, after which it started on its stable phase of 'stasigenesis'[3].

This process is revealed quantitatively for the first time in our studies of the linear values of P, C and T.

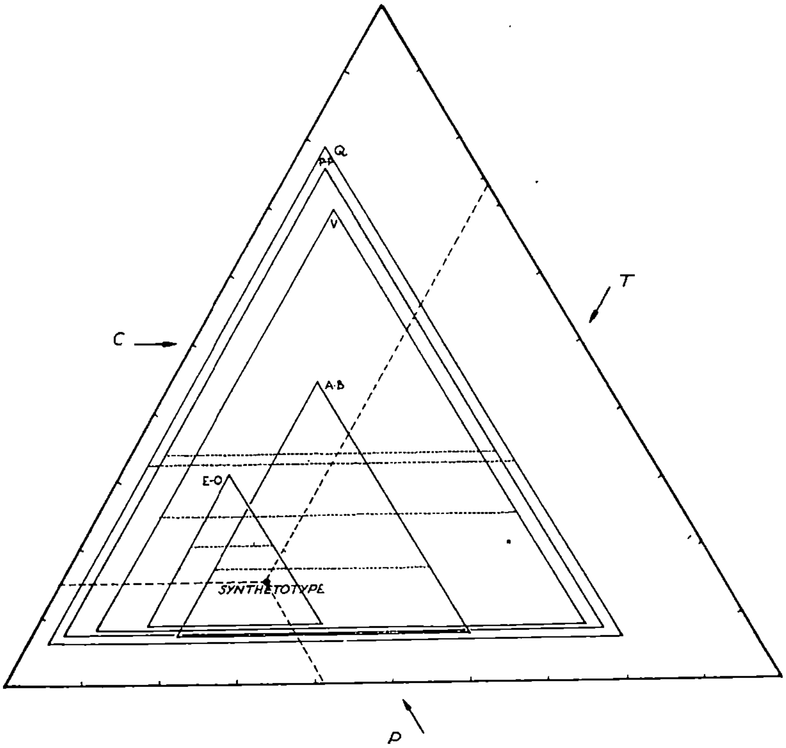

Fig. 1. Areas obtained by plotting on triangular co-ordinates of the measurements (expressed in percentages) of the lengths, P, premolar series to the paraconid of M_1; C, from the paraconid to the protoconid of M_1; and T, the remainder of the premolar series, in 133 species of living and fossil fissipede carnivores. The dotted lines represent the upper limits of the areas occupied by the different species. The broken lines are the co-ordinates of the synthetotype, *Cynodictis*. *E–O*, Eocene–Oligocene; *A–B*, Aquitanian–Burdigalian; *V*, Vindobonian; *P–P*, Pontian–Pliocene; *Q*, Quaternary

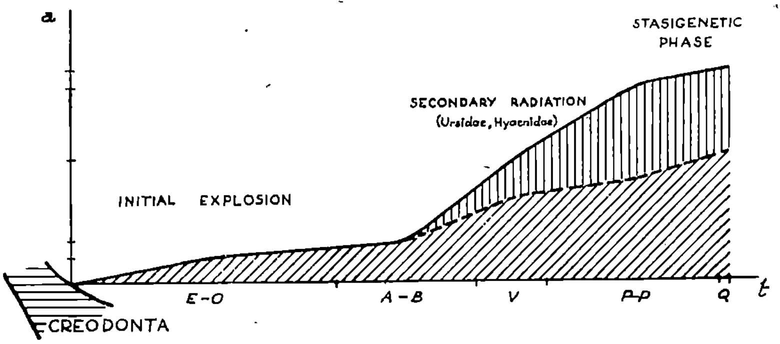

Fig. 2. Graph expressing the same data as Fig. 1, plotted on Cartesian co-ordinates. As ordinates, the amplitude of the variations expressing the increase in size of the areas of Fig. 1; as abscissæ, time expressed in absolute units. The broken line indicates the separation of the basal families from those of the Ursidae and Hyaenidae, the additive character of which is clearly shown

ersity College

The rate of increase in the area shown on the graph, representing fissipede evolution, changes in the Vindobonian, and the values obtained when represented as co-ordinates plotted against time provide a graphic expression of this phenomenon (Fig. 2).

Induction of Triploidy in the South African Clawed Frog, *Xenopus laevis* (Daudin)

When amphibian eggs are exposed to a temperature shock a few minutes after fertilization, the second maturation division may be suppressed, and, by fusion of the haploid sperm with the diploid egg nucleus, triploid embryos may result[1,2]. In the earliest experiments of this type prolonged treatment with low temperatures (0° to +3° C.) was employed on eggs of *Triturus viridescens*[3], but exposure of freshly laid eggs to a hot shock varying from 35–37° C. for from five to fifty minutes was found to be equally effective in this species[4]. These techniques have since been employed successfully on several species of Urodela and Anura. To the list of triploids produced experimentally, *Xenopus laevis* has now been added. This Anuran species is particularly suitable for this research, since reproduction can be induced throughout the year under laboratory conditions, and the young are easily reared, reaching maturity in less than one year.

Mating and ovulation were induced by injection of chorionic gonadotrophin ('Ciba' *Op.* 776). The newly fertilized eggs, collected at 16–18° C., were submitted to a temperature shock in the range of 34–39·5° C. This treatment, lasting 5 min., was applied 1–10, 10–20 or 20–30 min. after oviposition. The mortality attributable to the heat treatment increased with increased temperature.

After about two days at 20–22° C. the larvæ hatched and were swimming freely 2–3 days later. On the eighth to tenth day after hatching the tail-tips were amputated and made into permanent whole preparations according to Baltzer's tail-tip technique[5].

To find the degree of ploidy, I counted the number of nucleoli per nucleus in 100 epidermal cells of each tail-tip, and, where possible, also determined the chromosome number. In this way, I was able to show that in this species, as in the frog and the axolotl[6], the maximum number of nucleoli per nucleus corresponds to the number of chromosome sets.

Triploid *Xenopus laevis* are best obtained from eggs treated within 10 min. of oviposition with a temperature of 36·1–36·5° C., when about 54 per cent of the analysable larvæ are triploid. Altogether 339 triploids have been produced. Other heteroploids and chromosome number mosaics also developed from eggs exposed to temperature shock.

Triploids have been reared to maturity, but final results concerning their growth and physiology are not as yet available. A triploid male, approximately 2½ years old when mated to a diploid female, showed greatly reduced fertility, while two other triploids of the same age, showing female characters, did not spawn after injections of large doses of hormone. Gallien[7], and Chang and Witschi[8], showed that the female is heterogametic in this species. It appears, therefore, that the triploid homogametic males can be fertile, while the heterogametic triploid females have failed so far to produce eggs.

I wish to thank Prof. R. Meier (Chemical Industry, Basle) for the chorionic gonadotrophin used in this experiment. I am very grateful to Dr. M. Fischberg for his advice and interest in this work.

Epimorphic Regeneration during Hibernation

It has always been considered that certain factors must be present for normal epimorphic regeneration, and increase in temperature and certain metabolic activities are primary conditions which accompany regeneration.

An adult female tortoise of that species most commonly imported into Great Britain from north-west Africa and south-east Spain, *Testudo graeca graeca* L., was noted in the summer of 1954 to have a necrotic condition of the mental and first infralabial cephalic scales, this condition increasing to destruction of the larger part of the two dentary bones which constitute the distal part of the lower jaw. The tortoise lived through a spasmodic hibernation and was seriously handicapped the following summer, being prevented from normal mastication. The oral cavity was thus open to the exterior by this wound as the distal part of the lower jaw was now destroyed.

At the commencement of the second hibernation in 1956 the extent of the wound was some 4 mm. in length. While still in hibernation it was noticed that there had been closure of the ends of the wound. By the completion of hibernation two months later there was complete regeneration of the formerly affected parts of the lower jaw.

This example of epimorphic regeneration is of interest in that it occurred during hibernation and thus the temperature, oxygen and food levels were lower than those necessary for activity and voluntary response, the latter being associated with hibernation in poikilothermic animals. The total period occupied some twenty-three weeks, and of this time the pre-tissue regeneration stage took three quarters. This is approximately the time ratio for amphibian epimorphic regeneration.

FORTHCOMING EVENTS

Monday, January 27

Institution of Electrical Engineers, Radio and Telecommunication Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Informal Evening on "An Enquiry into the Specification of Transistors". Talk by Mr. F. F. Roberts.

Tuesday, January 28

Institution of Civil Engineers (at Great George Street, London, S.W.1), at 5.30 p.m.—Mr. W. Fillingham Brown, Mr. J. C. Wylie, Mr. G. E. G. Mattingly and Mr. J. Longwell: Formal Discussion on "The Disposal of Towns' Wastes".

Institution of Electrical Engineers, Radio and Telecommunication Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Symposium on "Long-Distance Propagation above 30 Mc./s.".

Women's Engineering Society, London Branch (at the Central Electricity Authority Headquarters, Winsley Street, London, W.1), at 6.45 p.m.—Mr. C. G. Barlow: "Food Instrumentation".

Wednesday, January 29

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Prof. A. R. Ubbelohde, F.R.S.: "The Marriage of Art and Science".

Institution of Electrical Engineers, Supply Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. J. L. Douglas and Mr. A. W. Stannett: "Laboratory and Field Tests on 132 kV. Condenser Bushings".

Institution of Mechanical Engineers, Education Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Discussion on "To What Extent Should Students be Penalized for Bad English in National Certificate Examination Papers?"

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Mr. I. Maddock: "Ultra-High-Speed Oscillography".

Thursday, January 30

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Mr. L. H. Finlayson and Prof. O. Lowenstein, F.R.S.: "The Structure and Function of Abdominal Stretch Receptors in Insects"; Mr. E. J. Denton and Miss Mary Ann Walker: "The Visual Pigment of the Conger Eel".

Linnean Society of London (jointly with the Systematics Association, at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Meeting on "The Higher Taxonomic Group", opened by Mr. E. J. H. Corner, F.R.S., and Dr. A. J. Cain.

Friday, January 31

Royal Astronomical Society (at Burlington House, Piccadilly, London, W.1), at 4.15 p.m.—Geophysical Discussion on "Geochemical and Radiometric Methods of Surveying". Chairman: Sir William Pugh. Speakers: Mr. S. H. U. Bowie, Dr. W. Bullerwell, Dr. J. E. T. Horne and Mr. J. S. Webb.

Institution of Mechanical Engineers (General Meeting in conjunction with the Internal Combustion Engine Group, at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Dr. W. Rizk: "Some Experimental Studies of the Mixing Processes and Flow Configuration in 2-Cycle Engine Scavenging".

Institution of Chemical Engineers, Graduates and Students Section (at Caxton Hall, Westminster, London, S.W.1), at 6.30 p.m.—Mr. P. W. Mason: "Instrumentation in the Chemical Industry".

Royal Institute of Chemistry, London Section (joint meeting with Brighton Technical College Chemical Society, at Brighton Technical College), at 7 p.m.—Mr. F. A. Paine: "Some Chemical Aspects of Packaging".

British Glaciological Society (joint meeting with the Cambridge University Meteorological Society, in the Geography Department, Downing Place, Cambridge), at 8.30 p.m.—Mr. G. Manley and Mr. C. D. Ovey: "Some Aspects of Climatic Change".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Sir Lawrence Bragg, F.R.S.: "Gemstones".

Saturday, February 1

British Interplanetary Society (in the Tudor Room, Caxton Hall, Caxton Street, London, S.W.1), at 6 p.m.—Dr. N. H. Langton: "Meteoric Hazards to Space Flight".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Demonstrator in Physics—The Registrar, The Manchester College of Science and Technology, Manchester 1 (January 31).

Assistant Physicist (with a good honours degree in physics) in the Physics Department of the Sheffield National Centre for Radiotherapy—The Secretary, Sheffield Regional Hospital Board, "Broom Cross", Tree Root Walk, Sheffield 10 (February 1).

Head of the Chemistry Department—The Registrar, College of Technology, Suffolk Street, Birmingham 1 (February 7).

Mathematician (Assistant Experimental Officer grade), to work in the Agricultural Research Council statistical group dealing with a wide range of agricultural subjects—The Secretary, School of Agriculture, The University, Downing Street, Cambridge (February 7).

Assistant Lecturer or Lecturer in Pure Mathematics—The Registrar, The University, Nottingham (February 8).

Assistant Lecturer or Lecturer in Statistics—The Secretary, The University, Exeter (February 8).

Demonstrator (with a degree in agriculture) in Agriculture, for duties on the University Farms—The Registrar, The University, Leeds 2 (February 10).

Analyst (B.Sc., B.Sc.(Agr.), or equivalent, with emphasis on chemistry) at Yanco Experimental Farm, Department of Agriculture, New South Wales, for duties which include research and routine chemical work associated with rice-growing problems—The Agent-General for New South Wales, 56 Strand, London, W.C.2 (February 12).

Senior Technician (A.I.M.L.T. or equivalent qualification, and preferably with experience in museum and histological techniques) in the Department of Anatomy, University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 12).

Assistant Lecturer (with an honours degree in psychology and additional training or experience in clinical psychology) in Clinical Psychology—The Registrar, The University, Manchester 13 (February 15).

Lecturer in Psychology at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 15).

Research Assistant or Junior Fellow in Aeronautical Engineering—The Registrar and Secretary, The University, Bristol (February 15).

Research Biochemist (with a university honours degree in science, with biochemistry as a major subject, plus a knowledge of microbiology and some postgraduate research experience) at the Regional Pastoral Laboratory, Division of Animal Health and Production (C.S.I.R.O.), Armidale, N.S.W., Australia, to join a team of scientists investigating the chemical, biochemical, agronomic and nutritional aspects of a general programme concerned with the utilization and management of pastures—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 208/104 (February 15).

Scientific Officer (with a first- or second-class honours degree in physics, chemistry or chemical engineering) at the Water Pollution Research Laboratory (D.S.I.R.), Stevenage, Herts, to undertake (*a*) laboratory studies and theoretical consideration of settlement of flocculating and non-flocculating solid particles in quiescent and flowing aqueous media, and (*b*) laboratory and pilot plant studies of influence of design of sedimentation tanks on flow of liquid through such tanks and on settlement of suspended particles—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting F.3/8A (February 15).

U.S. Rubber Company Postgraduate Research Student (with a good honours degree including chemistry) to read for a higher degree, working on cationic polymerization under the direction of Dr. P. H. Plesch—The Registrar, University College of North Staffordshire, Keele, Staffs (February 22).

Lecturer in Statistics—The Secretary, The University, Aberdeen (February 24).

Assistant Lecturer or Lecturer (with special qualifications in mathematical statistics and some interest in industrial and engineering applications) in the Mathematics Department—Head of the Mathematics Department, Imperial College of Science and Technology, London, S.W.7 (February 28).

Chair of Geography tenable at the London School of Economics and Political Science—The Academic Registrar, University of London, Senate House, London, W.C.1 (February 28).

Director of the Zoological Park, Auckland, New Zealand—New Zealand House, 415 Strand, London, W.C.2, or The Town Clerk, Town Hall, Auckland, New Zealand (February 28).

Lecturer or Assistant Lecturer in Psychology—The Registrar, The University, Hull (February 28).

Research Spectroscopists (2) (with a university degree of M.Sc. or Ph.D. in chemistry or physics, and preferably with some research experience in the general field of spectroscopy) in the Division of Industrial Chemistry (C.S.I.R.O.), Fisherman's Bend, Melbourne, Australia, to work on the following research topics: (*a*) development of the field of atomic absorption spectroscopy and its application to theoretical and applied problems, and (*b*) experimental and theoretical studies of electronic and vibrational spectra of co-ordination compounds in relation to structure—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 590/658 (February 28).

Wellcome Research Fellow in Zoology at the University College of Rhodesia and Nyasaland, to collaborate in work on the physiology of tsetse flies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 28).

Lecturer in the Department of Botany—The Secretary, The University, Edinburgh (March 1).

George Kelley Reader in Metallurgy—The Registrar, University Registry, Oxford (March 20).

Assistant Lecturer (Grade "B") to teach Organic and General Chemistry—The Clerk to the Governors, Northern Polytechnic, Holloway, London, N.7.

Lecturer (preferably with qualifications or experience in chemical engineering and practical experience in radiochemical work) in the Nuclear Technology Section of the Department of Chemical Engineering—Prof. P. V. Danckwerts, Imperial College of Science and Technology, London, S.W.7.

Metallurgist, Chemist or Physicist (with an appropriate degree), for work in the Information Department dealing with every aspect of the recording and transmission of information on the extraction, manufacture and uses of non-ferrous metals and their alloys—The Secretary, British Non-Ferrous Metals Research Association, Euston Street, London, N.W.1.

sity College of

Research Chemists (organic chemists with physical chemistry interests, especially kinetics, or similar), for work on oxidation and ozonolytic reactions—The Director of Research, The British Rubber Producers' Research Association, 48–56 Tewin Road, Welwyn Garden City, Herts.

Senior Laboratory Technician (male, with previous experience as technician or steward in biology)—The Department of Zoology and Comparative Physiology, The University, Edgbaston, Birmingham 15.

Senior Lecturer in Physics; a Senior Lecturer in High Polymer Science; and a Lecturer in Chemical Technology and/or Chemical Engineering—The Clerk to the Governing Body, Borough Polytechnic, Borough Road, London, S.E.1.

Senior Scientific Officer (with a first- or second-class honours degree in physics, and postgraduate applied research experience), to join a team of chemists and chemical engineers making fundamental and applied research studies in the inorganic chemical field—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berks, quoting Ref. 1663/34.

University Lecturer and University Demonstrators in Physics—Dr. F. B. Kipping, University Chemical Laboratory, Lensfield Road, Cambridge.

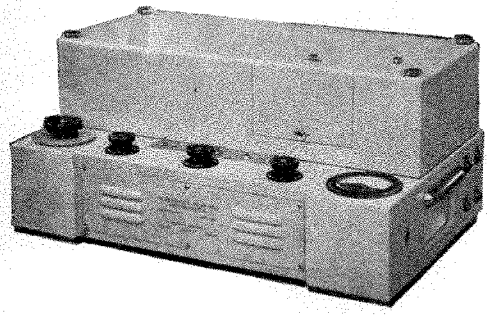
Have you realised the potentialities of near Infra-Red Analysis under high resolution?



For analysis and control, High Resolution has opened up a whole new field in the use of the near infra-red.

A high percentage of analyses previously thought possible only in the rock salt region are now being carried out on Mervyn Instruments.

Quantitative and qualitative analyses of many hydrocarbons are easily undertaken, chlorinated compounds of many types can be identified. Methods are available for the examination of complex phthalates. Heavy water analysis can best be carried out in the near infra-red.

Please write to Dept. IS/4 for the specification of the latest Mervyn N.P.L. INFRA-RED SPECTROMETER, together with additional data on analysis in the near infra-red, under high resolution.

LECTURES AND COURSES

UNIVERSITY OF BIRMINGHAM

DEPARTMENT OF MATHEMATICAL PHYSICS

GRADUATE SCHOOL IN MATHEMATICAL PHYSICS

The Graduate School in Mathematical Physics is intended for graduates holding a good honours degree in mathematics with subsidiary physics, who propose to take up work involving the practical application of mathematics to physical and similar problems. Candidates who are successful in the examination at the end of the course, will be awarded a Diploma in Mathematical Physics. The course lasts for one session (October to July). The fee is £58.

Application for admission to the course, starting in October, 1958, and requests for further information, should be made as soon as possible to the Registrar, University of Birmingham. In the case of candidates wishing to be considered for the advanced Course Studentships of the Department of Scientific and Industrial Research, it is desirable that application be made to the Registrar before February 15, 1958. In certain cases, a maintenance allowance with fees may be awarded by the university.

COLLEGE OF AERONAUTICS

The Board of Entry of the College invites applications from suitable candidates for the two-year course which begins in October, 1958, and ends in June, 1960. The course is intended for selected students of graduate standard. Candidates who do not possess a university degree may offer alternative evidence of educational attainment, for example, a good higher national certificate with a satisfactory record of apprenticeship or equivalent experience in industry. All applications are considered by the Board of Entry which may call candidates for interview. The College, a postgraduate institution, is devoted to the study of aeronautical science and engineering. The curriculum covers the five main subjects of aerodynamics, aircraft design, aircraft electrical engineering, aircraft propulsion, and aircraft economics and production. Instruction in the first year is designed to provide all students with a broad background of knowledge in all these subjects, with opportunity for limited specialization in two or three of them. In the second year students specialize more particularly, usually in one subject. The teaching in the syllabus is designed to fit students for a career in either aircraft or guided weapon engineering. Experiments in the air are an important part of the work, both in the first year when all students take part in them and in the second year when they are linked to the specialist work of the departments. Students who satisfactorily complete the course receive the Diploma of the College.

Further particulars and details of the procedure for enrolment may be obtained from the Warden, The College of Aeronautics, Cranfield, Bletchley, Bucks.

UNIVERSITY OF MANCHESTER

DIPLOMA IN BACTERIOLOGY

The course for the Diploma in Bacteriology requires full-time attendance in the Department of Bacteriology for one academic year (October-June). It is suitable for those who have qualified in medicine, veterinary medicine or other branches of science related to bacteriology. The course includes general and systematic bacteriology, bacterial chemistry, serology, immunology, virology, mycology and statistics. All candidates must present evidence of previous training approved by Senate as satisfactory for admission to the course and register as postgraduate students of the University.

Further particulars and forms of application may be obtained from the Secretary, Department of Bacteriology, York Place, Manchester, 13.

UNIVERSITY OF LONDON

TWO UNIVERSITY EXTENSION EASTER VACATION COURSES

1. METEOROLOGY

2. CURRENT TRENDS IN PHYSICS RESEARCH AND TEACHING

(in co-operation with the Meteorology and Physics Department of Imperial College)

Both courses take place at Imperial College, Prince Consort Road, South Kensington, London, S.W.7, from April 10-16. The courses are mainly for residential students but a limited number of non-residential students will be accepted. Applicants should normally be science graduates.

Applications to the Deputy Director (Ext. N), Department of Extra-Mural Studies, University of London, Malet Street, W.C.1, from whom further information may be obtained.

UNIVERSITY OF BRISTOL

DIPLOMA IN HORTICULTURAL SCIENCE

DIPLOMA IN PLANT PATHOLOGY (including ENTOMOLOGY) AND PROTECTION

The above postgraduate Diploma courses will be available during the Session 1958-9. Conducted in part at the Long Ashton Research Station, they are intended primarily for those with good honours degrees in science who seek careers in horticultural research, at home or overseas. The course in Plant Pathology and Protection permits specialization in any approved branch of the subject, including applied entomology.

The Horticultural Science course commences on September 15, the Plant Pathology course on September 29. Both courses extend over a full session of three terms ending in June or July, and include some additional practical work during the vacations.

Early application should be made to the Registrar, from whom full particulars may be obtained.

KING'S COLLEGE

(UNIVERSITY OF LONDON)

STRAND, LONDON, W.C.2

Applications for the B.Sc. Special degree course in Chemistry (commencing October, 1958) must reach the Sub-Dean of Science by January 31, 1958. All applicants (except those individually notified to the contrary) will be required to take a written examination in Chemistry at the College or at their school on Friday, February 21, 1958. Special examination arrangements may be made for applicants serving in H.M. Forces.

THE POLYTECHNIC

309 REGENT STREET, W.1

Six lectures on "Modern Methods of Oxidation and Reduction in Organic Chemistry" will be given on Fridays at 7 p.m., commencing February 21, 1958. Fee for the course: 11s.

Application forms and further details may be obtained from the Head of the Department of Chemistry and Biology.

J. E. RICHARDSON,
Director of Education.

GRESHAM COLLEGE, BASINGHALL Street, E.C.2. Tel. MONarch 2433. Four Lectures by Professor J. L. D'Silva, D.Sc., M.R.C.P. (Gresham Professor in Physic) on "Chapters in Medical Research" on Monday to Thursday, January 27 to 30.—The Lectures are free and begin at 5.30 p.m.

OFFICIAL APPOINTMENTS

GOVERNMENT OF THE UNION OF BURMA

The Geological Survey Department invites applications from experienced and qualified Geologists for the following vacancies: one Economic Geologist; one Engineering Geologist; one Ground Water Geologist; one Petrologist cum Mineralogist; one Petroleum Geologist; one Photo-Geologist; one Geophysicist. Applicants must be bona fide graduates and have a minimum of five years' practical experience. Contracts will be for a minimum of three years. Salaries range from £165 to £220. Transport and accommodation provided. Passage both ways for self and family. Supplementary experience in related fields such as spectrography, X-ray diffraction, differential thermal analysis, geochemical prospecting, etc., will be an asset.

Write to Director, Geological Survey Department, 226/230 Mahabandoola Street, Rangoon, Union of Burma, within one month from the date of appearance of this advertisement.

WEST OF SCOTLAND AGRICULTURAL COLLEGE

BACTERIOLOGY

Applications are invited for the appointment of Head of the College Department of Bacteriology. Applicants should have an honours or higher degree in science with extensive experience of teaching, advisory work and research in agriculture and dairy bacteriology. Salary scale Grade I (Intermediate) (men), £1,460 rising to £2,000 (plus temporary addition £75 at minimum graduated thereafter). Appointment on July 1, 1958, or as soon thereafter as may be agreed.

Full particulars from the undersigned, with whom applications must be lodged by March 15, 1958.

N. B. BAIN,
Secretary.

6 Blythswood Square,
Glasgow, C.2.

QUEEN'S UNIVERSITY

KINGSTON, ONTARIO, CANADA

POSTDOCTORAL FELLOWSHIPS

are available. Excellent research facilities. Ph cal and Organic Chemistry. Start October, 1 Write to Dr. J. B. Marshall, Awards Offi National Research Council, Ottawa, Canada, further details.

GRADUATE SCHOLARSHIPS

(value $1,800 upwards) leading to the M.A. Ph.D. degree are available. Start October, 1 Send personal history and references (Phy Chemists, Dr. G. B. Frost, Organic Chemists, J. K. N. Jones, F.R.S.), Queen's Univer Kingston, Ontario, Canada.

Latest date of application: **March 1, 195**

Up to $200 as advance of salary may be n to cover part cost of travel to Canada.

UNIVERSITY OF BRITISH COLUMBIA

DEPARTMENT OF PHYSICS

Applications are invited for appointments Lecturer, Assistant Professor, Postdoctorate Fell and Research Assistant in the Department Physics. The vacancies have been created by th rapid expansion of the university. They a mainly in the fields of nuclear physics, optic spectroscopy, solid state physics and geophys. Applicants should have an honours degree physics and, except in the case of Research Assis ants, a Ph.D. degree. They should not be mo than 30 years of age and should be available September, 1958. There are also Teaching Assi antships available to help students who wish pursue graduate work towards a Ph.D. degree.

Applicants wishing fuller information regardin any of these positions or awards should write t G. M. Shrum, Head, Department of Physics, University of British Columbia, Vancouver, B.C. Canada.

MARINE BIOLOGICAL ASSOCIATION OF THE UNITED KINGDOM

The Council of the Marine Biological Association, by arrangement with International Paint Limited, invite applications for the Researc Fellowship known as the International Paints Research Fellowship, to continue biological and chem cal research already in progress, including research with radioactive substances, at the Plymouth Laboratory, with a view to furthering knowledge of the effect of toxic substances on marine animals and plants. The appointment will be for a period of three years, subject to annual review, and the suitable applicant should be available to begin work on September 1, 1958. Salary will be conditioned by age and qualifications, and will approximate to scientific Civil Service scales. Applicants should preferably have had at least two years' postgraduate research experience, but recently graduated candidates would be considered. The post is appropriate both to biological and to chemical fields of research, but will be most suitably filled by a biochemist.

Forms of application may be obtained from the Secretary of the Marine Biological Association, The Laboratory, Citadel Hill, Plymouth, Devon, and should be returned to him in quadruplicate not later than February 15, 1958.

UNIVERSITY OF EDINBURGH

DEPARTMENT OF BOTANY

Applications are invited for the post of Lecturer in the Department of Botany. Salary scale £1,150 by £50 to £1,350 by £75 to £1,650 pe annum, with placement according to qualifications and experience, together with superannuatio benefit and family allowance where applicable. The person appointed will be responsible for a large First-year Class, and should preferably have a special interest in Cytology/Genetics. The successful candidate will be expected to take up dut on September 1, 1958.

Further particulars may be obtained from th undersigned, with whom applications (six copies giving the names of two referees, should be lodge not later than March 1, 1958.

CHARLES H. STEWART,
Secretary to the University.

MARINE BIOLOGY STATION

UNIVERSITY COLLEGE OF NORTH WALES

BANGOR

Vacancy for Technician on the scale £380 by £15 to £455; £485 by £20 to £545. Preference will be given to applicants with experience in workshop practice or histological techniques.

Applications, giving details of experience, together with the names of two referees, should be sent to the Registrar, U.C.N.W., Bangor, not later than February 15, 1958.

The BTL wide-range oven

This oven covers the range of 30°C to 300°C, with excellent heat-up and recovery characteristics. It can be used in three ways—as a **convection oven,** with vent open and without fan, as a **fan-circulated closed oven,** with vent shut and fan on, and as a **forced-draught oven,** with vent open and fan on.

B.S. 2648 readily achieved—conditions easily reproduced for repeat tests—stainless-steel chamber with removable shelves—10″ thermo-regulator scale plus built-in thermometer—TV suppressors.

The oven can be supplied with or without fan, which can easily be fitted later if needed.

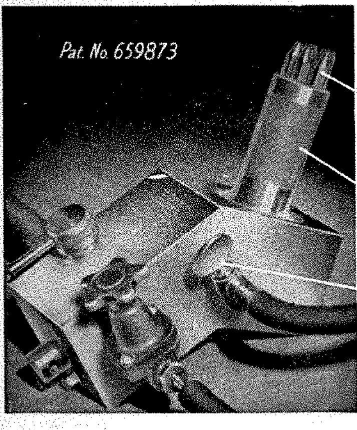
The Scorah OXY-COAL GAS BLOW PIPE



specially for working **BOROSILICATE GLASSES (Pyrex, Phoenix, Hysil, etc.)**

- ● Five jets and central pilot light — flame size selected INSTANTANEOUSLY.
- ● Rotating turret head for easy jet selection.
- ● Auxiliary supply of oxy coal mixture for hand torch.

Minimum oxygen consumption
Maximum economy

A modern oxy-coal gas blow-pipe of sturdy construction evolved through years of practical experience in glass manipulation. A nearly silent flame from pin point to one capable of working 100 mm. tubing at a flick of the turret. To the inexperienced it gives confidence, to the experienced it is an assurance of efficiency and successfully completed work. A unique instrument for the research laboratory or workshop. Send for Leaflet BP/N2.

BROADCASTING SERVICES AND EDUCATIONAL ACHIEVEMENTS

SOME three years ago, in March 1954, a Conference on Universities, Radio, Films and Television was sponsored by the Drama Department of the University of Bristol. In one of the papers contributed at this Conference, which were published for the University in 1956 (Butterworths Scientific Publications), Mr. E. Livesey, of the British Broadcasting Corporation, gave his definition of education: he suggested that it embraced the enlargement of horizons, the widening of experience and knowledge, both of the world outside the self and the nature of individual men, the awareness of the complexities of the world and of the human spirit, and through awareness the gradual acceptance of standards and ideals which have seemed to inspire the outstanding cultures and individuals both in the past and in the present. In short, it was in its effect on the uneducated section of the population that broadcasting had its greatest responsibilities and could make its greatest contributions. He also emphasized the great value in mass communication of the ability to interest a secondary audience as well as the primary one.

Mr. Livesey's remarks on the Third Programme audience, which he characterized as seekers and inquirers, as people with a certain attitude of mind or attitude to life rather than with a particular level of educational attainment, disposed of any idea of the Third Programme being a 'University on the Air', except perhaps in the sense in which the coffee-houses of the seventeenth and eighteenth centuries could be described as 'the penny universities', but he argued convincingly that the universities should take radio seriously. It was Dr. M. M. Lewis, director of the Institute of Education, University of Nottingham, who more specifically indicated the opportunities for the university, not simply in using mass media in its own internal teaching and in disseminating accurate knowledge about mass media and its relevance, but also in research. He stressed the importance of research on the conditions in which radio, cinema or television could become an effective medium, whether for the arts, as a means of communicating knowledge, or as an influence upon the attitudes of its audiences. He stressed also that it is important to ascertain if possible the relations between the components of each medium—the word as heard and the image as seen—and to understand the extent to which they reinforce or conflict with each other. Besides this almost entirely open field, there are the problems of the relations between these mass media and the written word, the effects of radio, film and television upon their audiences in the amount, quality and power of their reading.

It is even more apparent to-day than in 1954 that all this bears very closely, not simply upon education but also upon the whole fabric of public and social life. It may well provide, for example, the key to the social effects of equal opportunity to which Mr. W. James directed attention in a discussion at the Manchester Literary and Philosophical Society in March 1957. It bears equally on the problems of what may be described as cultural erosion, discussed by Mr. R. Hoggart in his book, "The Uses of Literacy", which have since found disturbing manifestations in other ways.

Perhaps the most disappointing feature of both the latest annual report of the British Broadcasting Corporation and of its Handbook for 1958* is that such problems are virtually ignored. The seriousness of such neglect is unmistakable to any thoughtful reader of Mr. Hoggart's book, as even his sub-title—"Aspects of Working-class Life with Special Reference to Publications and Entertainment"—might indicate. Writing with deep feeling and imaginative insight, Mr. Hoggart seeks to show that the under-educated in Britain—the three-quarters of the population whose schooling now ends at fifteen and whose distinguishing characteristic is rather lack of education than of money—are changing their traditional ways, and not for the better. Their freedom from poverty has exposed them to new and very deleterious influences, and while the gross prejudices and appetites are deliberately and even scientifically stimulated, the needs of the more serious-minded among them are neglected.

Mr. Hoggart achieves his purpose, and while he fails to offer much in the way of constructive suggestions and does not attempt to analyse the reasons why a minority resists this cultural erosion or to draw the distinction between this minority and the majority, both in its detail and in its comments his book displays the dangers in the present trends. It affords powerful support to Mr. Livesey's view that it is in the lesser educated section of the population that broadcasting has its greatest opportunities and responsibilities, and inevitably it arouses fresh doubts about commercial broadcasting. Once again the vital issue of the linking of power and responsibility is raised, and the reader may well reflect on the far-reaching consequences of the disappearance of independent newspapers and weeklies which contributed so much to sustain the creative minority on whom Mr. Hoggart relies to discharge a new and more difficult task, namely, that of waking the many from the hypnosis of immature emotional satisfaction.

Mr. Hoggart's study indicates sufficiently how much the responsible and constructive use of television and sound broadcasting could do to avert the dangers to which abuse of the mass-media—including the popular Press—expose us. He indicates, too, how this under-educated section of the community is losing its leaders and those best able to resist these blandishments. The implications and dangers of that process are set forth more fully, however, by Mr. James in his paper in *Manchester Memoirs* (98, 51; 1956–57) entitled "Social Effects of Equal Opportunity". Pointing out that although opportunity is still not equal and that serious-minded parents supply to their children incentives which are denied by those whose relaxations are the 'pools' and television, Mr. James emphasizes that one of the principal purposes of an educational system is to discover ability and encourage it. Men have always risen easily through the ranks of society in Britain; but to-day the selective process, abetted by the eagerness of industry to attract recruits of brains and character, is separating talent more efficiently than ever and leaving the great mass of the people, the base of the social pyramid, bereft of their natural leaders as never before.

---

* BBC Handbook, 1958. Pp. 288. (London: British Broadcasting Corporation, 1957.) 5s.

Mr. James suggests that the thinking of society is done in groups, some functional and artificial like a trade union or a clique of a social club, some natural and spontaneous like the company which meets in a particular bar parlour or golf course. These groups are not isolated but knit together through individuals, and opinion may flow easily from one to another. Just as Mr. Hoggart stresses the needs for individuals and groups to assert their individuality and to think and feel for themselves and not in the mass, so Mr. James suggests that for this system of many inter-related groups to function healthily, each group should be in its own way self-sufficient, throwing up leaders of a quality sufficient for the level of the group. A healthy group should be able of itself to supply all the human material necessary for a happy administration of the leisure time of its younger members.

An inescapable result of a selective system of education is a drawing off of all men and women with the intelligence that goes with natural leadership from the groups at the base of the social pyramid and their transfer to groups higher in the social scale. Accordingly, the more this draining-off of talent ministers to the competitive capacities of the nation as a whole by ensuring the widest reserves of managerial and technical skill for manufacturing industry, commerce and administration, the more important it becomes to deal with the social consequences involved. Mr. James mentions, for example, the starving of the trade unions of leadership of high quality, and the probability, now that most of those who do not climb out of their class lack the talent to do so, that the future trade union leader will be less able than his predecessor. Power will still remain with the elected man who has risen from the shop floor, and in consequence there may be difficult problems of authority, as always occurs when leadership and power are divorced from trained intelligence. Mr. James makes his point provocatively by suggesting that on the political side we might easily slip into a State-managed trade union system, and that on the social side a great extension of welfare work will be required. Be that as it may, it is obviously important that the fullest and wisest use should be made of such media as broadcasting and television to stimulate leadership and sound thinking.

For this to be done there must be clear ideas as to the functions and limits of broadcasting. It is here that the report of the Royal Commission on (Canadian) Broadcasting, which Sir George Barnes has well described as "a classic statement on broadcasting", more deeply thought out, better argued and more clearly expressed than any British or American document on the subject that he had read, is so valuable. The Commission assumes that the content of a country's broadcast programmes is important to it because they have entered into the lives of the people and changed them in ways that are often unobtrusive and unnoticed. Their influence will grow rather than diminish and we must adapt them to our use, accommodate them to our purpose and weave them into the fabric of our lives, so that on balance they are agencies for good and not for evil.

If radio and television are not to dull sensibilities by endless repetition of the commonplace and tawdry, or become dehumanizing forces, making all men and women conform in thought, action and aspiration to the lowest common denominator of their kind, the Commission is clear that there must be regulation not only of technical matters but also of programme content and station performance. It believes that there must be some externally enforced standards of public interest to strengthen the instincts of public service that many private broadcasters feel. While advertising has a value and place in the broadcasting system, it is a legitimate exercise of public control to see that a limit is placed on the results of commercial pressures.

The Commission, after a cogent analysis of the effects of mass advertising on broadcasting programmes, points out that if audience-rating rules supreme, broadcasters will allow programme-planning to sink to the most boringly uniform and low level, and the responsibility of the broadcaster to lead his audience by making available fresh entertainment and experiences will be lost. While recommending the retention of private broadcasting, it concludes that free enterprise has failed to do as much as it could do in original programme production and the development of Canadian talent, not because of a lack of freedom but because of a lack of boldness. Accordingly, the Canadian Broadcasting Corporation should remain; but it should have its task more clearly defined, should know the limits beyond which it is not expected to go and should have the means and the power to discharge that task within those limits.

Neither in Canada nor in Britain is there room for the confusion and hesitancy which seem to characterize the last annual report of the British Broadcasting Corporation. It is true that the report claims that the B.B.C.'s policy is based on the conviction that sound radio has a vital part to play in an age of television broadcasting, and it is true also that if sound radio is to remain vigorous and useful, reappraisals are necessary from time to time to determine the proper shape and scope of the programmes. Nevertheless, in spite of the affirmation that the B.B.C. intends to remain firm in its purpose and mission to serve the cause of education and the arts, and also to serve the community as a whole, including the majorities and minorities which constitute the community, there are indications that audience-rating may affect unduly the balance and even the content of the programmes.

The report shows that in the current year the number of combined licences for receiving sound radio and television will for the first time equal the number of licences for sound alone ; but it does not discuss the relation between existing expenditures on sound and television broadcasting, the cost of which (excluding the external services) in 1956–57 was £11·6 million and £9·1 million, respectively. The report observes that, apart from the effect of any continued rise in costs, it is doubtful whether the income in view is sufficient to maintain the present services and to introduce essential progress in television to meet competition—which is seen as a burden rather than a challenge. The present estimates include nothing for major new developments, and neither the report nor the handbook refers to the challenge presented by these new opportunities.

It is in this respect that the report and handbook must be criticized. No attempt is made to present the Corporation's financial needs as an investment which could yield rich dividends to the nation both in education and in public policy. It should be clear to even a casual reader of the Fowler Report on Canadian Broadcasting that the comparatively small sums required to enable the British Broadcasting Corporation to embark on the developments both in television and in broadcasting required to enable it to maintain its high standards and to use to the full its present opportunities could do much to offset the dangers of which Mr. James and Mr. Hoggart have warned us so clearly. It is even possible that a useful contribution could be made to technical education at trifling cost. As it stands at present, however, there appears to be real danger of declining standards as well as of missed opportunities. Clearly the British Broadcasting Corporation needs all the support as well as the stimulus which informed and percipient opinion can bring, if the very real dangers which attend the mass media of communication in the world of to-day are to be avoided. It is idle to think that Britain can achieve the standards in technical education, for example, which are so highly desirable, under the domination of an under-educated society. The greatly increased expenditure on technical and technological education will not be forthcoming or wisely applied without the guidance of a creative minority which can stimulate the changes in broadcasting and television and in other spheres of communication that could minimize or largely avert the danger.

FRANKLIN, THE NEWTONIAN

Franklin and Newton

An Enquiry into Speculative Newtonian Experimental Science and Franklin's Work in Electricity as an Example Thereof. By Prof. I. Bernard Cohen. (Memoirs of the American Philosophical Society, Vol. 43.) Pp. xxvi+657. (Philadelphia: American Philosophical Society, 1956.) 6 dollars.

THERE must be many to whom the title of this book will seem paradoxical. How can Franklin, who is usually remembered in science to-day as the inventor of the lightning rod, stand comparison with Newton ?

In fact, of course, no simple comparison is intended, although the author takes the opportunity of contrasting the comparative neglect with which he feels Franklin's scientific work is treated by scientists to-day with the prestige which it enjoyed among his contemporaries and successors. Franklin was "the first person out of the nation" to be awarded the Copley Medal by the Royal Society, and on his election to the Society he was given special privileges in the matter of fees ; in Parliament he was compared to "our Boyle" and "our Newton".

Franklin, a man without mathematical training, was in no position to master the forbiddingly mathematical "Principia". Newton's "Opticks", on the other hand, was more accessible, for its proofs are based on experiments. More significantly, it is not a well-rounded work like the "Principia"; Newton appended a list of 'Queries', to which he added as edition succeeded edition, and these 'Queries' showed the eighteenth century the directions in which the master's thoughts had been travelling and were at once an invitation to further research and indications of profitable lines of attack.

Prof. I. B. Cohen feels that modern students of Newton have tended to neglect the "Opticks" in favour of the "Principia", and that the immense influence of the former work has therefore been obscured. To do this is to take a one-sided view of Newtonian science, a side to which Franklin could not contribute. "It is, in fact, the purpose of this monograph to show that Franklin was a Newtonian scientist by displaying the many-sided character of Newtonian science in Franklin's day and by analyzing Franklin's own contributions to science in Newtonian terms" (p. 83). So, for example, "Franklin's outstanding contribution to the theory of electrical action lay precisely in his clear grasp of the value of Newton's speculative ideas and in his understanding of the importance of following the spirit rather than the letter of what Newton said" (p. 107).

The work is divided into four parts. In the first, the author comments on the history of science in general and introduces his two main characters with a discussion of their personalities and reputations. Part 2 deals with Newton's two principle works, and it includes a detailed discussion, which is further elaborated in an appendix, of his use of hypothesis. It is amusing to reflect on the importance which has been attached to Newton's dictum, *hypotheses non fingo*, in spite of the passages in the "Principia" clearly marked "hypothesis" and in spite of the many speculative hypotheses in the "Opticks".

Part 3 contains first a carefully documented account of various works of the early eighteenth century which were inspired by Newton's experimental philosophy and which Franklin is likely to have studied, and then a general discussion of Franklin's own place in the current of Newtonian science. In the last and longest part we are given a detailed account of the investigations into electricity in the eighteenth century, in which Franklin played a central part, and the book ends with a bibliography of nearly fifty pages and an index.

In spite of the excellence of the individual sections of the work, which are written with the authority of one who already has many contributions in the field to his credit, it is doubtful whether the somewhat disjointed thesis is adequate for so massive a work. The author himself recognizes that individual readers may wish to study only parts of the book, and he provides a detailed table of contents expressly for their convenience. But in spite of this defect in the work as a whole, the full and careful treatment which the individual topics receive will earn for Prof. Cohen the gratitude of all whose interests lie in this field.

M. A. HOSKIN

BRUNONIAN DOCTRINE IN MEXICO

El Brownismo en México

Un estudio critico, seguido de la primera edición de la version castellana que hizo en México hacia 1800, el Doctor Don Luis José Montaña, de los "Elementos de Medicina" del Dr. Juan Brown. (Cultura Mexicana, No. 14.) Pp. ii+311. (México: Imprenta Universitaria, 1956.) n.p.

DR. J. J. IZQUIERDO, who is professor of physiology in the University of Mexico and a well-known historian of medicine, has edited the Spanish translation of John Brown's "Elementa Medicinae" (1780) from a manuscript written about 1800 by Luis José Montaña (1755–1820), one of the most distinguished pioneers of medical teaching in Mexico. As a preface to the translation, Dr. Izquierdo contributes an interesting essay entitled "El Brownismo en México", which is also the title of the book.

It is a little difficult to understand why the author, who has already performed such useful service by editing Montaña's commentary on the Hippocratic works under the title "El Hipocratismo en México" (1955), should now regard Brown's treatise as worthy of similar attention. The "Elementa Medicinae" is by no means a medical classic. It was never taken seriously in Great Britain, and almost every medical historian, whether in Britain or abroad, regards Brown as a figure for derision and not for praise. Nevertheless, although in his own day he was a mere charlatan in the eyes of most of his colleagues, Brown was highly esteemed by many of his students and patients, and was well known on the Continent, especially in Germany, where, at the University of Göttingen, a riot between the rival factions concerning his doctrine was quelled only by military force.

John Brown, a schoolmaster of Duns, Berwickshire, who turned his attention to medicine and was a graduate of St. Andrews and a student at Leyden, became a pupil and secretary in the house of the famous William Cullen of Edinburgh, and at a later stage the bitter opponent and rival of the patron to whom he owed so much. Brown has been fitly called the Paracelsus of Scotland, since he was regarded by some as a genius and by others as a complete charlatan. The 'system', to which he laid claim as his own although it dated from the time of Asclepiades, was ridiculous in its simplicity. In his view health, and even life itself, was a response to continuous stimulation by warmth, food, fresh air, etc. When the stimuli were withdrawn, death resulted. Disease was caused either by excess or by diminution of stimulation. Consequently there were only two kinds of diseases, the *sthenic*, caused by too much stimulation, and the *asthenic*, caused by two little, or by depressive factors. Treatment consisted of the use of sedatives (usually opium) for the former, and of stimulants (preferably alcohol) for the latter. Such a simple and easy scheme of medical practice could not fail to attract the attention of physicians of that time, many of whom were perplexed and bewildered by the complexities of iatro-physics and iatro-chemistry, the twin theories which viewed the human body as a machine or a test-tube, and which had been introduced in place of the age-long theory of the 'humours'. 'Brownism', demanding little study or thought, appealed strongly also to students who welcomed relief from the burden of examinations. But there was a redeeming feature of the new system. Perhaps Brown, in spite of all his failings and fallacies, did actually perform a useful service in directing attention to the importance of the biological, as opposed to the physico-chemical, aspect of medicine. His doctrine may have formed a bridge, however frail and slender, between the scholastic age and the age of medical science.

Accordingly, we need not be surprised to learn that Brownism exercised some beneficial influence upon medical education in Mexico, a progressive country which could lay claim to the first hospital (1523) and the first organized medical teaching (1580) in the American continent, as well as to the first medical journal of the western world (*Mercurio Volante*, 1772). It does seem strange that Brown's "Elementa Medicinae" was translated into Spanish only twenty years after it was written, while Harvey's "De Motu Cordis" appeared in a Spanish version only after a lapse of more than three hundred years (1936). The reason was that Brown's work, at the time of its appearance, seemed to offer an easy solution to nearly every problem in medical practice, whereas Harvey's treatise, though infinitely more significant, remained misunderstood and devoid of practical outcome for many years. It was, in fact, born far ahead of its time, whereas Brown's answer to a pressing need was eagerly grasped and widely applied as soon as it appeared.

Dr. Izquierdo has therefore been fully justified in adding this curious chapter to his former studies of the early progress of medical education in Mexico. We are too apt to forget that the early history of medicine in Latin America had important repercussions throughout the civilized world and that it is a subject well worthy of our attention. The present volume is a fitting sequel to the author's splendid work on "Montaña y los origines del movimiento social y cientifico de México", and a fine tribute to the ancient medical school. It also serves to remind us that the phenomenon of the 'Brunonian System', or as the writer calls it, 'Brownism', despite its absurd simplicity, helped to divert medical thought, in Mexico and elsewhere, away from the traditional and often sterile theories, and towards the beginnings of the scientific basis which lies at the root of all real progress in modern medicine.

DOUGLAS GUTHRIE

REPRODUCTION IN FUNGI

The Physiology of Reproduction in Fungi

By Dr. Lilian E. Hawker. (Cambridge Monographs on Experimental Biology, No. 6.) Pp. vi+128. (Cambridge: At the University Press, 1957.) 15*s*. net.

METHODS of reproduction in fungi have both a general and a special interest—general, inasmuch as reproduction is fundamentally important to all organisms, and special, for the following reasons. As a group, the Fungi exhibit a remarkable variety of reproductive mechanisms, the overall effects of which are to ensure the dispersal of the species to fresh habitats and its survival over periods when growth is not possible. The factors which control reproduction are thus of considerable practical interest in the case of the many fungi which bring about disease in higher plants. They are also of special interest to the fungal systematist, because reproductive mechanisms form the main basis for fungal classification. Furthermore, a large proportion of fungi can be grown under standardized cultural conditions and, as compared with most other plants, they offer great conveniences in ease of handling, in inexpensiveness of apparatus required and in the speed with which the life-cycle of many of them can be completed. It is not surprising, therefore, that much physiological work, dealing with reproduction and other activities, has been carried out with fungi, and it is a safe guess that, in the future, many of the more fundamental studies of growth and reproduction in plants will be based upon the same material.

Dr. Hawker's compact monograph gives an up-to-date and critical digest of the literature bearing on the subject. After a short introduction, in which the main reproductive types are briefly described, there follows an account of the growth of spores and spore-bearing structures. This chapter is important, as it is only when the succession of developmental stages is worked out with some precision that one can pose the physiological questions that are involved. This comes out very clearly with the more complicated fruit bodies, for example, of Basidiomycetes—as in Corner's detailed studies—but it is equally certain that there is an elaborate succession, on a more microscopic scale, of stages in the development of the simplest kind of reproductive structure, such as an oidiospore. The physiological work proper is discussed in four main chapters, the last of which deals with the intricate and still controversial problem of sex in fungi. A short final chapter considers the sporing behaviour of a number of fungi in the field, as interpreted in the light of experimental work in the laboratory. A list of some 350 selected references closes the monograph.

As the author ruefully remarks more than once, the physiological study of fungal reproduction has as yet barely progressed beyond the empirical stage. It deals almost entirely with the effects of environment —temperature, light, *p*H, quantity and quality of food supply, etc.—on sporulation. There is much diversity, as between one fungus and another, in the precise effects produced by any one environmental factor and very few generalizations have as yet emerged. This is not surprising, for it is the conditions inside the mycelium, as produced by the external environment, that control the onset, the amount and the kind of sporulation. The story, as it is unravelled, will undoubtedly be a biochemical one, with sequences of enzymatically and hormonally controlled reactions. There is already good evidence of the functioning of sex hormones in some of the lower fungi.

Sexual reproduction in fungi differs, in one very important respect, from that in higher plants. In the latter the key problem is: Why do diploid nuclei, after an indefinitely long series of mitotic divisions, suddenly undergo a reduction division, thereby giving rise to the reproductive cells? With fungi, the problem is the converse: Why do haploid nuclei, after a like series of mitotic divisions, suddenly become associated in pairs which, sooner or later, fuse to form a diploid nucleus, which in turn immediately reduces to the haploid condition? Clearly, any progress in either of these fields will have repercussions in the other.

The great merit of this book is that, though short, it covers the ground and, in particular, indicates where the many gaps in our knowledge lie. Its value to the research worker in mycology is obvious, for there are research problems, of a more general or a more special kind, to be picked from almost every page.

W. Brown

SOIL SCIENCE

The World of the Soil

By Sir E. John Russell. (The New Naturalist: a Survey of British Natural History.) Pp. xiv+237+26 plates. (London: William Collins (Sons) and Co., Ltd., 1957.) 25*s*. net.

THE "New Naturalist" has nearly fifty volumes to its credit in the ten years of its history. The excellent contributions made by these volumes in the various fields of science already constitute a tradition. The editors' choice of author for a book on soil science could scarcely have been more auspicious, for Sir John Russell is internationally known to agriculturalists and soil scientists as director of Rothamsted Experimental Station for thirty years and as author of "Soil Conditions and Plant Growth". This present volume will introduce him to a wider audience for whom study of the soil is an absorbing hobby.

The arrangement of the subject-matter recalls the separate departments of any soil research institute. Soil geology, soil physics and soil organic matter are briefly but adeptly handled in the opening chapters and are followed by a more lengthy treatment of soil microbiology and zoology. Chapters on soil fertility and soil survey complete the book. The whole is written so admirably that the impression gained is never of a vast catalogue of research but rather of a living story simply told. One-third of the book is devoted to the micro-flora and fauna, and here Sir John excels. A fascinating array of bacteria, fungi, mites, arthropods, nematodes as well as earthworms, slugs and snails are discussed. Since Darwin's study of the earthworm, published some seventy-five years ago, has recently been reprinted, the relevant pages of the book under review are particularly apposite, for we are treated to an authoritative appraisal of Darwin's experiments—one could almost wish for more. The mole, the pad-mark of which graces the dust cover, receives but short shrift from the author; yet there are hill pastures which will never see the plough where the mole is an active soil-former.

To the gardener in search of do's and don'ts, the chapters on soil fertility are probably the most interesting. The development of the modern fertilizer industry saw the birth of Rothamsted. The progress towards modern balanced fertilizers tailored to specific crops is a tale which cannot be told too often. Organic cranks are summarily dealt with: compost returns to the soil only what it has taken from it—should any element be lacking, composting will only perpetuate the trouble.

The final chapters deal with soil classification and soil survey; the soil is discussed in relation to the landscape and consideration is given to the uses to which the land can be put. This has been successfully done for southern Britain, but little is said of that large part of northern Britain once heather moor and now, due to the herculean labours of the crofters who reclaimed it, fertile and pleasant agricultural land. Such is Auchallater Farm in Glen Cluny (Plate XXII, which has both these places misspelt).

There are few printer's errors. On p. 144 the reference p. 000 is not helpful; Table 7, p. 94, has some curious arithmetic. The photographic illustrations are excellent as is also the drawing of the nematode (facing p. 114), but that of the crustaceans (p. 124) is lamentable, and Figure 9 (p. 136) cannot be regarded as useful. Very occasionally, too, the author nods: neutrality is stated to be pH 7·2; the meaning of the paragraph at the bottom of p. 145 is obscure; on p. 209, bilberry is said to be associated with wetter bogs, whereas it is an indicator of drier conditions. Crowberry could be substituted.

Altogether this book is one of "New Naturalist's" best. As a record of achievement for those who share Sir John's calling, it is heartening reading. The book, however, is intended for the lay reader. Apart from occasional OH's, NH_2's and COOH's, all terms are defined in the text. There is no glossary and none is needed. The words of a former proposer of a vote of thanks to Sir John can be quoted here: "The lecturer 'as been hintelligent, but not too hintelligent for us". P. C. DeKock

RED SEA FISHES

Fishes of the Red Sea and Southern Arabia

By Henry W. Fowler. Vol. 1: Branchiostomida to Polynemida. Pp. v+240. (Jerusalem: The Weizmann Science Press of Israel, 1956.) n.p.

THIS book and the two volumes expected to follow it will constitute the only compendious account of the fishes of the Red Sea since Klunzinger's of 1879. It is compiled, not by a man who has had special opportunities to study Red Sea fishes, but by a courteous, now very senior gentleman, who sits in a small upper room in the Academy of Sciences of Philadelphia, armed with a great facility in line drawing, a long experience and a very fine index to fish literature. The work is offered, not as a contribution to knowledge, but as a tool for those able to study the fauna.

As such we must be grateful for it, and ordinary standards of criticism should perhaps not be applied. Those who will approach the Red Sea fauna for the first time with this as their key should be warned, however, to use it very critically, and only for preliminary determinations. Many of the species extend over the whole Indo-Pacific area, and if Mr. Fowler had no Red Sea specimens at hand, nor a description of such to copy, he drew up a description from a specimen from perhaps Honolulu or the Philippines. He explicitly disclaims, therefore, any ability to contribute to the question of geographical variation or subspeciation.

The telegraphic style of the descriptions will probably be understood by readers whose first language is not English, but more care for punctuation would have helped here.

On nomenclature Mr. Fowler is pitiless. It seems regrettable that decisions made in such a careful work as that of Bigelow and Schroeder on the sharks and rays of the western North Atlantic should not have been taken as standard. They have carefully considered the arguments for and against the use of *Carcharhinus* for a large genus, the type of a family, of sharks. In the end, the decision had to be arbitrary, and in the interests of stability they gave it for *Carcharhinus*. So far as Mr. Fowler is concerned, this work was in vain. He uses *Galeolamna*.

It is significant that the work is published in Israel, largely in answer to the needs of the young scientists at work there. No doubt Mr. Fowler would join us in the hope that among them are some who will eventually put it out of date.

E. Trewavas

ADVANCES IN JUNGIAN PSYCHOLOGY

New Developments in Analytical Psychology

By Michael Fordham. Pp. xiv+214. (London: Routledge and Kegan Paul, Ltd., 1957.) 25*s*. net.

THIS book is by one of Jung's disciples and deals with the philosophy of his school. The author was a founder member of the Society of Analytical Psychology and is a Fellow in child psychiatry at the London Child Guidance Clinic.

No doubt enthusiastic Jungians will enjoy reading it but others will feel exasperated and frustrated by the loose thinking. For example, on p. 23 the author states, "Jung points out that the concept of conservation of energy is based on age-old archetypical forms and Pauli shows how Kepler's scientific discoveries are linked with symbolic doctrines of great antiquity". It is, of course, easy to do this sort of thing, and one can always find a myth to fill the bill, but there is not one iota of evidence to prove it. Again on p. 107 he states, "It is well known that children love fairy and folk tales and will concentrate on them for hours, demanding repetition of particular stories over and over again. This phenomenon can only be understood in terms of activity of archetypes within the psyche of the child". But this is untrue. It can be understood otherwise if we are willing to try. A child wants to hear a story re-told again and again either because it gives it pleasure or dispels anxiety, or both at once. We do not need to drag in hypothetical archetypes to explain it.

The author is best with his description of children's neuroses, as one might expect from his training, and in this field his work is more acceptable.

Clifford Allen

The Organization of British Central Government, 1914–1956

A Survey by a Study Group of the Royal Institute of Public Administration. Edited by D. N. Chester. Written by F. M. G. Willson. Pp. 458. (London: George Allen and Unwin, Ltd., 1957.) 32*s.* net.

THIS corporate work provides a detailed account of the structure of British Government and the changes which have occurred since the beginning of the First World War. After reviewing the general pattern, each of the major fields of Government is surveyed in turn: finance, trade and industry; law, justice and public order; social services; external affairs; defence; common services; and scientific research. For that last chapter alone the book is of great interest to the scientist. It brings together scattered information not easily available, some of it new or unfamiliar to most scientists, and provides a more penetrating survey of government scientific organization in the civilian field than is contained in the pamphlet issued under that title in 1951. It lifts the veil slightly on the work of the Committee of Civil Research and shows how much Lord Balfour did to establish the position of science in Government. The concluding chapters in the central co-ordination of Government and the handling of administrative change, besides providing a factual account of the present arrangements, including the way in which the Lord President of the Council came to assume major responsibility for the country's scientific effort, gives some first information about the Cabinet Machinery of Government Committee appointed in 1942.

The great value of these two chapters lies in the clear exposition of the various factors to be taken into account in determining the structure of Government, for example, in deciding on the number of ministries or the grouping of functions, and in doing so they indicate precisely what is involved in proposals to centralize or decentralize scientific activities, including research, among others. Essentially a work of reference, the book is provided with notes and a bibliography which will facilitate further inquiry in directions likely to throw more light on aspects of the organization of science in Government now being debated. The book is thoroughly up to date, recording, for example, the changes last April in responsibility for nuclear energy.

Organic Chemistry

Electronic Theory and Reaction Mechanism. By Rowland I. Reed and Dr. S. Horwood Tucker. Pp. viii+108. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1956.) 15*s.*

THE 'organic chemistry' of the title is restricted to those aspects of theory covered by the subtitle; there is no description of preparations and properties. The contents consist of nine chapters on the electronic theory and its application to organic reactions, and two on reaction mechanism. The chapters deal with: the atom, the origin of valence, acids and bases, atomic and molecular orbitals, intermolecular influence of atoms and groups on valency electrons, physical methods of measurement, physical evidence for conjugative electron shifts, interatomic distances, the hydrogen bond, reaction mechanism, and substitution reactions. The terminology and the theoretical contributions of Ingold and his school receive considerable notice. Mesomerism (resonance), hydrogen bonding and the other new theoretical developments which have extended and revolutionized our ideas on molecular structure are very clearly explained. The new knowledge leads to the formulation of helpful generalizations, affords a deeper understanding of reaction mechanism, and indicates a more logical classification of descriptive matter. To older chemists and university freshmen desirous of studying the application of the electronic theory to organic chemistry, this book is recommended.

G. Fowles

Statistical Tables for Biological, Agricultural and Medical Research

By Prof. Sir Ronald A. Fisher and Dr. Frank Yates. Fifth edition, revised and enlarged. Pp. x+138. (Edinburgh and London: Oliver and Boyd, Ltd., 1957.) 24*s.* net.

STATISTICIANS are well served in the matter of tables. The two standard sets, of which this is one (*Biometrika* Tables being the other), are beautifully printed and, by current standards, remarkably cheap. They run to new editions sufficiently frequently for continual additions and improvements to be possible.

This fifth edition of Fisher and Yates follows its predecessor of 1953 in general design, but incorporates several new tables and some extensions of former ones. Most of the material concerns variate-transformations, new tables being provided for 'logit' and complementary 'loglog' transformations, and the table of angular transformations is enlarged. A new table for the application of the product-ratio method in linkage investigations in genetics is also supplied.

Science and Human Life

Successes and Limitations. By Prof. J. A. V. Butler. Pp. viii+163. (London and New York: Pergamon Press, Ltd., 1957.) 15*s.* net.

THERE are quite a number of books of a popular, or semi-popular, type dealing with the urgent problems of the day thrown up by the advance of science and the tensions inseparable from human life. Prof. Butler has produced a handy little volume, in line with the general run of such works: it is interesting enough, but one may ask for whom exactly is it intended. The two sections, "Science and the Individual" and "Science and Human Society", cover adequately the fields suggested by their titles. But they contain very little beyond what can be garnered from ordinary contemporary reading. This result is not the author's fault; science *qua* science in everyday affairs is not what many people are worrying about. The difficulty is 'why' rather than 'how'; and having regard to Prof. Butler's point—manifestly correct—that intrinsic intelligence, apart from training and opportunities, has not increased greatly through the ages, the main need is for deeper philosophical insight at the point at which science ends, and faith or revelation may be said to begin.

The list of suggested books for further study contains several of a decidedly advanced character. On balance, they will conduct the reader into regions of thought not specifically scientific in the narrow sense (under Chapter 7 there is a misprint: 'Kaffka' should be 'Koffka'). But this may be all to the good, and Prof. Butler will have provided a sound introduction.

F. I. G. Rawlins

A NEW DEAL FOR AUSTRALIAN UNIVERSITIES

By Sir ERIC ASHBY

President and Vice-Chancellor, The Queen's University, Belfast;
formerly Chairman of the Professorial Board, University of Sydney

INTRODUCTION

On November 28, 1957, the Prime Minister of Australia, Mr. Menzies, announced in the House of Representatives in Canberra that the Commonwealth Government proposed, subject to co-operation from the States, to raise Commonwealth expenditure on the State universities from about £6,000,000 in the triennium 1955–57 to £22,000,000 in the triennium 1958–60. This is support on a scale beyond the dreams of Australian academic men a few years ago. It represents an act of statesmanship on the part of the Commonwealth Government. More than this, it provides at long last an opportunity for Australia's intellectual development to keep pace with her dramatic political and economic development.

The circumstances which led up to this historic announcement are as follows. In Australia, education is a responsibility of the States, not the Commonwealth. After the War, the cost of higher education increased steeply in Australia, just as it did in Britain. The States increased their grants to the universities by 123 per cent (although their revenue increased by only 77 per cent); nevertheless, these increases were insufficient to meet the universities' needs. The Commonwealth had come to the financial help of the State universities during and after the War to enable them to give higher education to large numbers of ex-servicemen; and in 1950 Commonwealth help was stabilized in a formula whereby the Commonwealth gives to each State, for its universities, £1 for every £3 of revenue the universities receive from State grants and fees. The Commonwealth commitment is limited to a ceiling of grant in any one year. Capital grants for buildings and equipment have not normally been provided by the Commonwealth Government.

There have been signs for some time that this machinery would soon become quite inadequate to finance the universities of Australia. The urgent demand for graduates, the unprecedented pressure of young people wanting higher education, the frustration among academic men in many university departments, have together precipitated a situation which could be resolved only by a drastic review of the whole of Australian higher education. This review has now been published*. In December 1956 Mr. Menzies asked a Committee of five, under the leadership of the chairman of the University Grants Committee in Britain (Sir Keith Murray), to inquire into such matters as "the role of the university in the Australian community; the extension and co-ordination of university facilities; technological education at university level; and the financial needs of universities and appropriate means of providing for these needs". The other members of the Committee were Sir Ian Clunies Ross, formerly a professor in Sydney and now chairman of the Commonwealth Scientific and Industrial Research Organization (C.S.I.R.O.); Sir Charles Morris, vice-chancellor of the University of Leeds and sometime chairman of the Committee of Vice-Chancellors and Principals; Mr. A. J. Reid, chancellor of the University of Western Australia and formerly head of the State Treasury; and Mr. J. C. Richards, assistant general manager of the Broken Hill Proprietary Co. (B.H.P.). The Committee worked for three months, and has produced what Mr. Menzies described in his speech as a "brilliant and provocative report".

SUMMARY OF THE REPORT

The Background

The report begins with a lucid and restrained chapter on the role of universities in the community. It then goes on to describe the economic and educational setting of Australian universities: a population of 10 million increasing at a rate of 2½ per cent per annum and likely to reach 12 million by 1967; capital investment at the level of some £1,500 million in a year; primary industries with an output of more than £1,000 million; and international responsibilities under the Colombo Plan, the South-East Asia Treaty Organization, and the South Pacific Commission. All these activities need to have behind them healthy and adequately financed universities. The need for teachers is so desperate that in one State bursaries are offered to children "at the tender age of eleven plus if their parents express an inclination for them to become school teachers". The shortage of graduates is not confined to scientists and technologists: there is an unsatisfied demand also for graduates in arts, law and medicine.

There is no lack of recruits for these occupations. The school population increased from 1·1 million in 1946 to 1·8 million in 1956; but there is a severe wastage of talent at secondary school level through early leaving. In 1954, only 9·4 per cent of seventeen-year-old children were receiving any sort of full-time education. Nevertheless, some of the universities are, on British standards, large. A list of them, with their 1957 enrolments, is given in Table 1.

In 1956 the total recurrent income of all the universities was about £11·78 million, of which 79·5 per cent was provided by State and Commonwealth grants and 15·6 per cent came from fees.

---

* Report of the Committee on Australian Universities. (Commonwealth Government Printer, Canberra, Australia, 1957.)

Table 1

University and foundation date	Enrolment, 1957*
Sydney (1850)	7,407
Melbourne (1853)	6,341
Adelaide (1874)	3,331
Tasmania (1890)	750
Queensland (1909)	3,519
Western Australia (1911)	1,661
Australian National University (1946)	67
N.S.W. University of Technology (1949)	4,288
New England (1954)	591
Canberra University College (1930)	216
Newcastle University College (1951)†	—

* The enrolments are full-course equivalents, calculated as follows: full-course student = 1, part-course student = ½, external student = ¼. Some full courses at the N.S.W. University of Technology are designed for part-time students. The gross enrolment for 1957 was 36,465.

† Enrolments included under New South Wales University of Technology, of which it is a branch.

Present State of the Universities

Some departments in the larger universities are in a state of chronic congestion. First-year classes of more than 1,000 are not uncommon, and failure-rates are alarmingly high. For example, 30 per cent of holders of Commonwealth scholarships (of which 11,536 were awarded in 1955) fail to graduate. It is commonly believed that students come to the universities inadequately prepared and not sufficiently mature to benefit from university teaching; and of course the size of elementary classes makes any tutorial tuition in the first year very difficult. It has been an Australian tradition to admit all qualified applicants to universities and not to exercise any machinery of selection. The Committee realized the great practical difficulties in the way of limiting entry or raising matriculation standards, and it recommends that Australian universities should equip themselves to deal with the increasing flood of students coming to them, rather than protect themselves against the flood by putting up barriers to entry.

The Committee commented adversely not only on the high failure rate (which it describes as a "national extravagance which can ill be afforded") but also on the very low ratio of honours to pass degrees and the very meagre development of postgraduate work. The pattern of a large undergraduate department is illustrated by the Department of History in the University of Sydney in 1956. History i had an enrolment of 768; History ii, 332; History iii, 119; and History iv (the honours year), 11; and for this total enrolment of more than 1,200 students there is a full-time academic staff of ten. Accommodation in many departments is "bursting at the seams". Halls of residence (most of which in Australian universities take the form of 'colleges' under church endowments, but which do not impose religious tests on their residents) are quite inadequate. This is particularly serious because of the considerable Asian student-population now to be found in Australian universities and because about half the population of Australia lives away from the big metropolitan centres. Academic staffs were reported by the Committee to be disheartened not only by enormous elementary classes and small honours schools, but also by other difficulties. Their salary scales were low by comparison with those of other professional men (the Prime Minister alleviated this difficulty by including in his announcement a substantial lift in salary-scales). The superannuation system does not allow of easy migration of staff between universities and C.S.I.R.O., or even between all universities. In most universities the staff have no adequate common room or meeting place. For years there has not been enough money for libraries, equipment and technical assistance; and the high cost of travel is an obstacle to the sort of inter-university conferences and meetings which would be a great stimulus to academic men.

Problems Ahead

To these old difficulties, which many academics have endured heroically and successfully overcome, formidable new difficulties will shortly be added. Numbers in the 15–19 year age-group actually fell between 1947 and 1952. They rose by 16·4 per cent during 1952–57. Between 1957 and 1962 they are expected to rise by 36·4 per cent. Enrolments in universities are expected to increase from 36,465 in 1957 to 70,785 in 1965. A first-year chemistry class, which to-day has an enrolment of 1,400, may in ten years time have to deal with an enrolment of 3,000. Sydney expects by 1965 to have a student population of 27,000 (17,000 in the University of Sydney and 10,000 in the New South Wales University of Technology).

The Committee's Proposals

The Committee deals calmly and firmly with these alarming expectations. The main need is for money. Following the Committee's recommendations, the Commonwealth Government has offered to contribute over the triennium 1958–60 more than £9 million toward a proposed capital programme of £15 million; emergency grants totalling £4½ million to enable universities to dispose of their most severe embarrassments before 1961; a contribution towards a substantial increase in salaries; and £600,000 towards the extension of residential accommodation in colleges. In addition, the Committee recommends, and the Government accepts, that the Commonwealth contribution for running expenses should be raised by 10 per cent per annum for the triennium 1958–60.

But the Committee has not confined its comments to finance. It suggests that consideration should be given to some sort of close link between the Australian National University, which is a purely postgraduate institution, and Canberra University College, which prepares undergraduates for Melbourne degrees. It is in favour of a second Victorian university in Melbourne and it foresees the need for the expansion of the New South Wales University of Technology to include a second medical school in Sydney, and indeed to become a second full-range university, which might appropriately be called the University of New South Wales.

Of particular interest are the Committee's very frank comments on policy-making in Australian universities. The governing bodies of the State universities are comprised (as they are in the Scottish and modern English universities) predominantly of laymen, with some representation from the teaching staff. The body of professors (commonly called the Professorial Board) is charged, as it is elsewhere, with a good deal of responsibility over academic matters. But by an accident of history, the vice-chancellor in most universities is not chairman of the body of professors, nor is he their spokesman and protagonist before the governing body. These responsibilities fall to a chairman of the Professorial Board who is elected by the professors. Accordingly, the vice-chancellor finds himself immobilized in the performance of what should be one of his chief functions: to maintain the delicate balance between the lay governing body and the academic staff, and to prevent any suspicion of an employer–employee relationship arising between them. It may well be that the chairman of the Professorial Board performs this function adequately, but (as the Committee says) "this position tends almost automatically . . . to place the vice-chancellor in some other camp" (that is, other than the academic camp). "There comes to arise . . . not a natural unity of governing body and academic, but a natural disunity".

One consequence of this anomalous position of vice-chancellors is that outside their universities, too, they find it difficult to formulate nation-wide policy on academic matters. Consequently, there is a lack of cohesion between universities. This, and the absence of a common initiative, are criticized by the Committee as weaknesses which must be overcome if Australian universities are to discharge their present and future responsibilities.

An Australian University Grants Committee

The Committee's chief long-term recommendation is that an Australian University Grants Committee should be set up, with a full-time chairman, two lay members and five academic members. The Committee emphasizes that the members should not be representatives of Commonwealth, States or universities, but should serve solely in their personal capacities. It should be set up informally, not by statute, and attached to the Prime Minister's Department. Its business should be to advise the Prime Minister on the contributions which the Commonwealth should make to States toward the support of universities, and directly toward the support of the two university institutions under Commonwealth control. The Committee hopes that the States would be willing to seek advice from the proposed University Grants Committee in respect of their local university problems. The proposed Committee would work very much as its prototype does in Britain, by visiting universities and preparing a recommendation for the Commonwealth Government. The Committee believes that financial grants should be made at three-yearly intervals, not five-yearly intervals as in Britain.

Finally, the report reminds its readers that the provision of money and the setting up of a University Grants Committee will not of themselves solve Australia's problems of higher education. The Committee, if it is set up, will have to rely on the Australian universities, through their Vice-Chancellors' Committee, to formulate a national policy for the development of higher education and to take the initiative in putting their views before the proposed University Grants Committee. The Committee would (as in Britain) deal directly with each university over its own programme of development. But it would also have to be in frequent consultation with the Australian Vice-Chancellors' Committee on matters of national policy.

COMMENTARY

To anyone familiar with Australian universities, this report is a masterpiece of discernment, and the Prime Minister's quick response to it is very gratifying. The older Australian universities have a great tradition of scholarship. The intellectual capacities of Australian youth are as high as those of young people anywhere in the Commonwealth. Already in her brief history Australia has made very distinguished contributions to science, scholarship and world affairs. But in recent years her universities have been taxed hopelessly beyond their capacities. The trouble is due partly to the peculiarly Australian conception of democracy which regards the right to attend a university as something in the same category as the right to drive a vehicle on the public highway. But public enthusiasm for enjoying the benefits of higher education has not been matched by public enthusiasm for paying for them. So the universities have had to open their doors to students inadequately prepared to enter and in numbers for which no proper provision had been made; the outcome has been a decade of mass-education, lectures in duplicate, practical classes without enough demonstrators, shortages of equipment, heavy examination failures, and no energy left over for research.

Mr. Menzies's announcement, and his promise that a body having the functions of a University Grants Committee will be set up, disperses most of the clouds in the academic sky. But not all. It still remains to be shown whether a university organized on the Scottish pattern can carry a student population of 14,000–17,000 (as Sydney contemplates) without a breakdown in the machinery of administration. You cannot double the size even of a football team without changing the rules of the game. It is a matter of judgment, of course; but one cannot observe these large Australian universities without wondering whether they should not either re-organize their administration on the American model (with permanent deans and much more decentralization of business into faculty offices), or limit numbers to (say) 8,000 and encourage the foundation of new institutions.

In the long view (not as a way to meet the present emergency) there is something to be said for dispersing the enormous and amorphous elementary classes into colleges somewhat resembling the American junior college. In a country without a strong sixth-form tradition in its schools and with such a widely dispersed population, the educational climate might prove congenial to colleges in the country and in the suburbs of big cities, where young students under personal supervision could cover the intermediate year in basic arts and sciences. Such an arrangement as this would reduce the numbers in the universities; it would provide them with more mature students; and it would enable them to preserve their Scottish pattern of organization.

However, the Committee was wise not to make any revolutionary or unfamiliar proposals in this report. For there is no time to be lost, and the only way Australian universities can prepare for the macro-bulge which is coming is by a vigorous programme of development on conventional lines which the vast majority of academic people will approve. The Murray Committee has made a decisive contribution to Australian higher education; in doing so it has put not only Australians, but also all other academic men in the Commonwealth, in its debt.

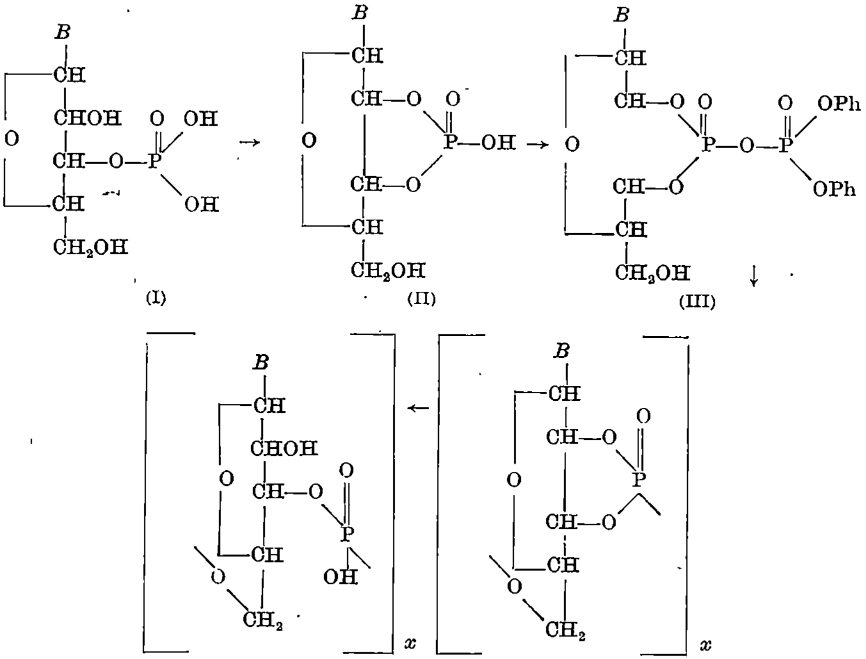
SYNTHESIS OF RIBONUCLEIC ACID

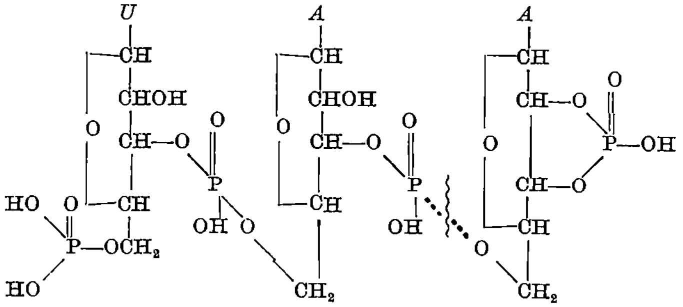
By Dr. A. M. MICHELSON

Arthur Guinness, Son and Co., Ltd., Chemist's Laboratory, St. James's Gate, Dublin

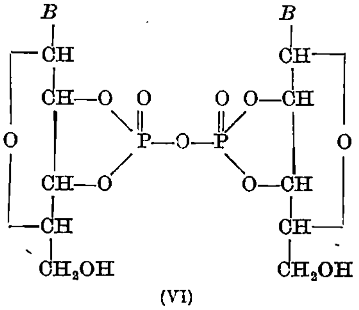
WHILE classical methods have been applied with some success to the synthesis of small polynucleotide derivatives such as dithymidine dinucleotide[1] and adenosine-2′-uridine-5′-phosphate[2] such methods give low yields and require protected nucleoside and nucleotide derivatives. The fully esterified mixed anhydride method has proved successful for di(nucleoside-5′)-phosphates[3], but when applied to the synthesis of a naturally occurring type of internucleotide linkage is unsatisfactory[1]. An extension of this method to the use of nucleoside phosphite anhydrides has been described[3]; but again, yields are low and the method offers little hope for the synthesis of higher oligonucleotides. A preliminary publication by Khorana[4] describes the use of carbodiimide and toluene-*p*-sulphonyl chloride in the synthesis of deoxydinucleotides from thymidine-5′-phosphate.

In view of the difficulties attending the use and removal of protecting groups in the ribonucleotide series, the possibility of polymerization of the readily available 2′(3′)-monoribonucleotides has been examined. It has been found that these nucleotides are easily converted to the nucleoside-2′-3′-cyclic phosphates[5], which are then polymerized quantitatively, by the action of tetraphenylpyrophosphate at room temperature. A number of such polymers have been prepared, including polyadenylic acid, polyuridylic acid and polymers containing adenylic and uridylic acids in various proportions. By using uridine-2′ : 3′-cyclic phosphate-5′-phosphate in the presence of excess adenosine-2′ : 3′-cyclic phosphate, polymers of adenylic acid terminating with uridine-5′-phosphate at the head and adenosine-2′ : 3′-cyclic phosphate at the tail (V) have been synthesized. In addition, by reaction of a mixture of four mononucleotides—adenosine-2′(3′)-phosphate, guanosine-2′(3′)-phosphate, uridine-2′(3′)-phosphate and cytidine-2′(3′)-phosphate—a synthetic 'ribonucleic acid' has been prepared.





(V)



(VI)

In practice, a solution of the mono tri-*n*-octylammonium or mono tri-*n*-decylammonium nucleotide (I) is treated with tetraphenyl pyrophosphate[6] or diphenyl phosphorochloridate[7] and tri-*n*-butylamine to give the cyclic phosphate (II) quantitatively, which is then made to react *in situ* with a further mole of tetraphenylpyrophosphate (added directly or formed in the reaction medium by addition of diphenyl phosphorochloridate). Rapid polymerization, with the evolution of heat, then occurs, presumably through an unstable pyrophosphate (III), which then reacts, either directly or via the dinucleoside pyrophosphate (VI), with the primary hydroxyl groups to give ultimately a mixture of polymers (IV) with 2′(3′) : 5′-phosphate linkages and a tail 2′ : 3′-cyclic phosphate. Precipitation from the reaction mixture gives the crude product, which can be fractionated roughly into oligonucleotides of various molecular weights by acid precipitation, or better, by dialysis against water, 0·5 *M* ammonium chloride and 2 *M* sodium chloride solutions. Representative dialysis results are given in Table 1.

Table 1

	Dialysis of crude polymers against		
	Water	2 *M* sodium chloride	Dialysis residue (per cent)
Commercial ribonucleic acid (from yeast)	14·8	29·8	55·4
'Synthetic ribonucleic acid'	18·5	43·3	38·2
Polyuridylic acid	31·8	45·7	22·5
Polyadenylic acid	24·9	45·5	29·6
Polyadenylicuridylic acid	19·8	46·6	33·6

The properties of these polymers are consonant with the general structure ascribed to natural oligonucleotides[8] with the exception that, as expected, only some 50–60 per cent of the internucleotide linkages are 3′-5′, the remainder being 2′-5′. (While this is perhaps unfortunate from a purely æsthetic view, the possible chemotherapeutic value of such compounds may be significant.) Thus mild acid treatment opens the terminal cyclic phosphate to give oligonucleotides with tail units containing a 2′(3′)-phosphate. More vigorous acid degradation gives either purines and/or pyrimidine-2′(3′)-phosphates, depending on the polymer. The polymers are completely degraded by 0·1 *N* sodium hydroxide at 37° for 24 hr. to the respective 2′(3′)-mononucleotides (and to uridine-2′(3′) : 5′-diphosphate in the case of P5′UP5′AP5′AP—abbreviations as in ref. 1) only. Treatment with rattlesnake venom gives the expected nucleosides, and, after prolonged treatment, the nucleoside-2′(3′) : 5′-diphosphate (that is, the tail nucleotide) in small amount[9]. Estimation of the relative amounts of nucleoside and nucleoside-2′(3′) : 5′-diphosphate gave an estimate of the average molecular size. Thus the unfractionated initial products gave results varying from 4·2 to 7·8 nucleotides as the average chain-length. Preliminary work indicates that under the conditions employed the molecular species vary from 2 to approximately 10 nucleotides in length. While the reaction can undoubtedly be improved it does not seem likely that extremely large polymers with molecular weights of the order 50,000–10^6 will be synthesized in this manner unless an anhydride which is effective in aqueous solutions is used.

While the polyadenylic acid was resistant to the action of ribonuclease, some 50–60 per cent of the internucleotide linkages of polyuridylic acid were cleaved. This figure is aproximate as only a proportion of the material appears as uridine-3′-phosphate, the remainder appearing as di-, tri- and possibly tetra-nucleotides (paper chromatography) containing 2′-5′-internucleotide linkages exclusively. Considerable variation has been observed, and it is likely that under suitable conditions a higher proportion of 3′-5′-linkages would be formed[10,11].

It is clear from the extensive work of Sir Alexander Todd and his collaborators[12] that, under the conditions employed, the nucleoside-2′ : 3′-cyclic phosphates would be polymerized by the action of any acid anhydride where the weaker acid of the anhydride is stronger than the cyclic phosphate. It was therefore of interest to examine the action of an anhydride such as that derived from diphenyl phosphoric acid and benzyl phosphorous acid[13]. When adenosine-2′ : 3′-cyclic phosphate was treated with diphenyl phosphoric–benzyl phosphorous anhydride[13], approximately 50 per cent of the adenylic acid was converted to polymers containing a 5′-benzyl phosphite group at the head and a cyclic 2′ : 3′-phosphate at the tail. The remaining 50 per cent was isolated as adenosine-2′ : 3′-cyclic phosphate-5′-benzyl phosphite, identified by its conversion to adenosine-2′(3′) : 5′-diphosphate[14] via adenosine-2′ : 3′-cyclic phosphate-5′-benzyl phosphate and adenosine-2′ : 3′-cyclic phosphate-5′-phosphate.

By using dilute solutions of the nucleoside-2′ : 3′-cyclic phosphates and allowing the reaction to proceed for a limited time, products containing relatively large amounts of smaller oligonucleotides were obtained. Dr. L. A. Heppel of the National Institutes of Health, Bethesda, Maryland, has examined such products from adenosine-2′ : 3′-cyclic phosphate and has tentatively identified AP5′A2′ : 3′P, AP5′AP5′A2′ : 3′P and AP5′AP5′AP5′A2′ : 3′P by comparison with authentic specimens. Treatment of AP5′A2′ : 3′P with dilute acid gave AP5′AP from which the terminal 2′(3′)-phosphate was removed by the action of prostate monoesterase to give a mixture of A2′P5′A and A3′P5′A. Spleen phosphodiesterase split approximately 50 per cent of the AP5′AP to AP, the remaining A2′P5′AP being resistant to enzymatic cleavage.

It is hoped to extend the work to the synthesis of dinucleoside phosphates and the alkyl esters of the 2′- and 3′-nucleotides.

Thanks are due to Dr. L. A. Heppel for the results mentioned, to Dr. A. K. Mills for interest and encouragement and to the Directors of Arthur Guinness Son and Co. (Dublin), Ltd., for permission to publish this work.

BIOCHEMICAL FUNCTIONING OF VITAMIN B_{12}

By DR. E. LESTER SMITH, F.R.S.
Glaxo Laboratories Limited, Greenford, Middlesex

THE chemical structure is now known not only of vitamin B_{12} itself but also of many natural and biosynthetic analogues and products of its chemical modification. It is therefore possible to begin to consider such problems as the linkage between the vitamin and peptides or proteins (the intrinsic factor, for example) and the nature of the molecular groupings that may be involved in its biochemical functioning. The 'nucleotide' has two points of attachment to the porphyrin-like 'planar group'. One is through a chain of seven atoms between ring *D* and the phosphorus: the other is by a co-ordinate link between the cobalt and N3 of the benziminazole. It is this second link that is broken in the formation of the purple dicyanocobalamin with alkaline cyanide, leaving the nucleotide part hanging loose, as it were, from its long chain with considerable freedom of movement; this, incidentally, may well be what prevents the dicyano compound from crystallizing. It appears that this link can also be broken by thiocyanate[1], and there is some evidence that linkage with B_{12}-binding proteins also extrudes the nucleotide in this fashion. Thus the two complexes, between vitamin B_{12} and intrinsic factor and the sow's whey factor, respectively, have both been shown to retain the —CN group, and they both fail to react with alkaline cyanide to add a second —CN: this suggests that the position is already occupied, by a group not readily displaced by cyanide[2,3].

Most of the vitamin B_{12} present in animal or bacterial cells appears to be 'bound', presumably to proteins, so that one probably should consider such a complex, rather than the free vitamin, as the biologically functional unit. It is already becoming clear, however, that any one of various slight modifications to the vitamin structure can interfere with its linkage to a highly specific binding factor. This suggests multipoint attachment, such as has been envisaged between enzymes and their substrates[4], involving both the nucleotide and the planar group. The cobalt might well be joined to a nitrogen atom of a histidine residue[5], and one can envisage the nucleotide, on the end of its flexible chain, being free to wrap itself around part of the protein molecule so that, for example, oppositely charged and suitably situated sites on the two molecules are in juxtaposition. It would not then be surprising if the absence of one or both of the methyl groups from the dimethyl benziminazole, or their replacement by other relatively non-polar groups (even by chlorine), made little difference to the biological activity, as indeed it does[6]. This part of the molecule probably represents, as it were, just the end of a line of hooks, by which the vitamin attaches itself to its appropriate biological environment. For the same reason, perhaps, in microbiological systems synthesizing cobalamins, this part of the molecule is freely replaceable by almost any substituted benziminazole one cares to add to the medium or (with a more limited range of organisms) by one of several purines[7]. Reverting to the biological activity of analogues, one may note that even a hydroxyl group on the benzene ring is enough to depress activity considerably, and that exchange of benzene for the more basic pyrimidine ring (to give a purine type analogue) almost entirely destroys activity except for the less specific assay organisms[6]. It is justifiable to conclude that the low activity of the purine analogues is due to their inability to link effectively with specific proteins, because the adenine-containing pseudo-vitamin B_{12} does not interfere (even when it is present in large excess) with the binding of vitamin B_{12} by intrinsic factor or with the uptake of the vitamin from the gut[8,8a].

It seems likely that the highly activated β-position on ring *B* must also be involved in binding to specific proteins. It is this position that is attacked when the vitamin is subjected to mild oxidation by halogens or by oxygen and alkali. The adjacent acetamide chain is then modified and cyclized to yield a lactam or lactone ring fused to ring *B*; these compounds are also biologically inert[9].

Having thus dismissed a good deal of the molecule to accommodate the protein, one is left wondering which parts are left to function in promoting enzyme reactions. A likely answer seems to be the labile amide groups. There are three of these, one much more labile than the others, and they are almost certainly those on the three propionamide chains: it is perhaps significant that these chains protrude from the planar group on the side opposite to the —CN group, that is, on the side where the binding protein is probably located. Thus at least one would be in a position to interact with a substrate molecule anchored in turn to the protein.

These amide groups can be successively hydrolysed with dilute acid or alkali, and the resulting mono-, di- and tri-carboxylic acids are not merely inert towards the B_{12}-requiring mutant of *Escherichia coli*, but they show some anti-vitamin activity. This appears to be enhanced when the acids are converted into substituted amides by reaction with methylamine, aniline, etc. (conveniently with dicyclohexyl carbodiimide as condensing agent)[10,11]. One may deduce that these substituted amides can compete successfully with the vitamin for binding sites on the specific protein (which some other analogues cannot do) but that they are unable then to fulfil its biochemical functions[8a].

The precise nature of these functions is still something of a mystery. So many, indeed, have been attributed to vitamin B_{12} that most or all of them must be indirect, and the problem is to discover what reaction or reactions are directly B_{12}-dependent and so fundamental that they could have an over-riding effect upon the others. Most investigators have, wisely perhaps, kept to their own corners of the field, and few have attempted much by way of integration. One can, however, discern four totally different hypotheses that have been tentatively proposed.

Dubnoff in early *in vitro* experiments detected an effect of a vitamin B_{12} concentrate upon the reduction of —S—S— linkages to sulphydryl groups. This was taken up by Bacon Chow, who pointed to the low serum glutathione-levels in B_{12} deficiency states, quickly raised to normal by the vitamin, and linked this with a possible effect in maintaining —SH enzymes in the reduced, active state. Since important glycolytic enzymes are in this group, the connexion between vitamin B_{12} and carbohydrate metabolism could thus be explained[12]. The established function of the vitamin in promoting the *de novo* synthesis of the methyl group of methionine from one-carbon precursors in a higher oxidation state must involve at least two steps. Since a folic acid derivative is probably responsible for the actual transfer to homocysteine of a one-carbon unit, it seemed reasonable to postulate that vitamin B_{12} reduces this to $—CH_3$ and perhaps also homocystine to homocysteine[13]. The trivalent cobalt in the vitamin can indeed be reduced reversibly to the divalent state, in which it could serve as a reducing agent, and although the redox potential seems well outside the physiological range, linkage to protein might change it in the required direction. However, there are difficulties; for one thing vitamin B_{12} sheds its cyanide group on reduction and probably also the ability to link with protein. Also, recent experiments appear to disprove any effect on the reduction of homocystine[14].

In lactobacilli, vitamin B_{12} can be replaced by thymidine or other deoxyribosides. The assumption that their synthesis is controlled by the vitamin has recently been confirmed. Further, tracer experiments suggest that the synthesis of deoxyribose is the B_{12}-dependent step. Although these phenomena could not be demonstrated with other species of micro-organisms, it was widely assumed that vitamin B_{12} was concerned in the synthesis of deoxyribonucleic acids, and possibly of ribonucleic acids also, in animals and humans. This was supported by the dramatic increase in red cells and growth of epithelium (relief of sore tongue) on treatment of pernicious anæmia cases. By analogy with the methylation of homocysteine, vitamin B_{12} was supposed to bring about methylation of uracil to thymine (possibly at the nucleoside-level) and so to make available this constituent of deoxyribonucleic acid required for cell division[13]. This hypothesis has also run into difficulties. Doubt has been thrown upon some evidence cited in its support. More directly, recent tracer experiments by Connor Johnson and his colleagues have failed to show any effect of vitamin B_{12} upon the rate of synthesis of either deoxyribonucleic or ribonucleic acid from any of several likely precursors by pigs or chicks[15].

A number of observations have indicated that cyanocobalamin is involved in protein metabolism. Other experiments did not support this as a major role, and until recently there was a tendency to regard any such effects as secondary. Several independent studies have, however, given indications of diminished concentrations of different enzymes (transmethylase, ribonuclease and dehydrogenases[16–18]) in the tissues of B_{12}-deficient animals. Wagle and Connor Johnson have recently reported that the incorporation of carbon-14 labelled serine or glucose into liver protein of pigs or rats is markedly diminished when the animals are deprived of the vitamin[19]. They have also demonstrated large *in vitro* effects in experiments with liver and spleen microsome fractions from normal and deficient animals. The incorporation of labelled amino-acids was about four times as great in the '$+B_{12}$' preparations; moreover, the '$-B_{12}$' ones could be brought up to nearly the normal level by addition of the vitamin[20]. This is the most dramatic effect yet demonstrated in an isolated enzyme system. However, other workers have criticized the experimental conditions and are not yet ready to concede proof of a *direct* effect upon protein synthesis.

A complication in advanced pernicious anæmia is degeneration of the spinal cord, and this condition can be arrested only by vitamin B_{12}, whereas folic acid can bring about hæmatological remission, at least temporarily. Niewig and his colleagues were forced to the conclusion that this implied a control of protein synthesis by vitamin B_{12}, because the protein turnover rate is high in the nerve axons involved in these degenerative changes[21]. Being wedded to the nucleic acid hypothesis, they explained this as an indirect effect, whereby ribonucleic acid functions as a template for protein synthesis, the synthesis of the necessary ribonucleic acid being the B_{12}-dependent step. However, it would be more logical to cite this evidence in support of a direct effect of the vitamin upon protein synthesis. This hypothesis can explain better than most the over-riding effect of cyanocobalamin upon a number of metabolic processes, if it functions by controlling synthesis of the protein moieties of enzymes.

Wokes and Picard[22], noting increased thiocyanate excretion in dietary vitamin B_{12} deficiency, diminished by administration of the vitamin, have put forward a hypothesis based on the supposed lability of the cyanide group and competition of hydroxocobalamin and the enzyme rhodanese for cyanide.

One may now inquire which of these hypotheses accords best with the picture of a vitamin B_{12}-protein complex with its labile amides poised for action. Although no precise mechanism can be envisaged as yet, the likely answer seems to be the protein-synthesis hypothesis, as indeed its latest exponent, Dr. Connor Johnson, has suggested[23]. It is perhaps relevant that an enzyme, recently detected in liver, catalyses the exchange of ammonia from protein amide groups for aliphatic amines, including the ε amine group of lysine[24].

The end of the story is not yet in sight, but there are reasonable hopes that we may soon know more about the mode of action of vitamin B_{12} than we do about some other vitamins discovered much earlier.

MANAGEMENT AND RESEARCH

THE theme of the annual conference of the British Institute of Management, which was attended by 620 top managers during November 6–8 at Bournemouth, was set in the opening address by the Right Hon. Viscount Monckton of Brenchley. Introducing research as a signpost to better management, Lord Monckton showed that as a nation we are devoting roughly two per cent of our national income to research of all kinds. This appears to be a similar proportion to that for the United States, but our research effort seems to be more dominated by defence requirements, particularly in the fields of aircraft, electronics and atomic energy, than is that of the United States. Partly, if not wholly for this reason, a larger share of the financial burden in Great Britain is carried on the shoulders of the Government. The expenditure of the United Kingdom Government on research and development in the year 1955–56 amounted to more than £200 million, of which only about one-sixth was accounted for by expenditure on civil research. Lord Monckton paid tribute to the important contribution to industrial efficiency which is made by the research activities of business undertakings within their own organizations —activities entailing expenditure many times greater than that of the Government on industrial research— and also raised the basic question of whether, in principle, the consumer of the current products of industry should be called upon to cover the cost of research designed to produce better and cheaper articles for his successors, or whether such ventures should be properly financed by the shareholder by way of lower dividends or by the direct provision of new capital.

Giving pointers for future research, Lord Monckton suggested that "it might be worth while for some internal research to be done on the actual effects upon particular branches of business of changes in rates of purchase tax". Research of this kind might yield results of value in shaping the processes of national economic policy in such a way that full regard is paid to its more remote and long-distance consequences as well as its immediate and direct effects. Another field would be research into "the true causes of breakdowns in employer–workers relations".

The remainder of the Conference was a model of how large national conferences should be organized to give all participants opportunities of obtaining information and discussing matters in which they are particularly concerned or interested. In twenty-five sectional meetings topics ranged from electronic data processing to market research; from operational research to case-studies of successful new companies; from economic research to means of evaluating performance in the sales force; from the use made by industry of research organizations to budgetary control.

One of the liveliest of these sectional meetings was concerned with psychological factors in group relations. The speaker was Dr. A. T. M. Wilson, of the Tavistock Institute of Human Relations, who indicated the main types of investigations which have been made into group relations. By the use of experimental discussion groups, two styles of group leadership were contrasted: the highly directed and the 'actively integrative'. The investigator concluded that the integrative style leads to a more appropriate group atmosphere, to greater group satisfaction with the performance of members, and to greater member satisfaction with group solutions of problems.

Another type of research into group relations has been the descriptive analysis of group relations exemplified by the studies of Woodward and her colleagues with Manchester dock workers, and Scott and his colleagues at the University of Liverpool on the effects of changing methods of steel manufacture on the social structure and group relations in a mill. Similar work has been done by Trent and Bamforth, who, in a study of the longwall system of mining, have presented one of the most detailed analyses yet available of group relations in a production system; Burns has recently examined cliques and cabals in industrial firms, while Mackenzie has discussed the relationship between production and inspection groups.

Studies of the kinds described are adding to our knowledge of group relations in actual working situations beyond the superficial level at which they have often been described and considered in the past. More important, they illustrate how knowledge can be deepened by the use of a systematic framework derived from the social sciences. The full value of such studies will not be easy to assess until it is possible to see their results in the new generations of managers whose training has in part been based on discussion of such research and its implications.

A different kind of study has been made with the experimental reorganization of working groups in actual industrial situations. One of the best-known is that of Rice, who, in an Indian textile factory, had an opportunity to initiate an experiment in complete reorganization of a working team, first in an automatic and later in an ordinary weaving shed. With the agreement of management and trade unions, and with the collaboration of the workers concerned, he was able to reconsider the whole basis of dividing up the activities needed to service the working looms. In the automatic weaving shed he reduced the twelve categories of job to three and completely altered the supervisory pattern. The results were to increase efficiency by about fifteen per cent. A completely reorganized managerial system emerged.

One extremely important finding of this work can be expressed as follows: the technological character of a particular production system does not completely determine the structure of the working team by which any such system is operated. The studies which Rice has published demonstrate the possibility that there may be much to be gained from a consideration, first, of the objectives of a particular production team and, secondly, various possible forms of team structure.

Studies of communication in small working groups have also been made and clearly showed that communications are particularly vulnerable to the creation of informal procedures, and the creation of 'by-pass channels', and that the existence of informal procedures can serve as a signal to the investigator to look for discontent originating in circumstances perhaps quite unrelated to communications themselves.

rsity College of Sci

There have been many experimental training conferences in group relations, and these have varied patterns of component activities. Wilson also described the use of groups; theory sessions: role-playing; and short projects to illustrate the project method of teaching.

In the ensuing discussion it was made clear by management representatives that useful research findings in group relations would continue to be unused until their interpreters were able to free themselves from unnatural jargon and obscurantism.

Confusions about productivity and profits were analysed by R. J. Brech (Unilever Ltd.), who showed that productivity is of little value in assessing the current operations of a firm.

Productivity is simply an arithmetic ratio expressing a technical concept. It describes the relative change in output from a given change in input. If output goes up or down more than proportionately with the increase or decline in input, then productivity increases or declines. As a technical concept it has its value, since once it is known, changes in output can be predicted for given changes in input. But from a management point of view, such a concept has little significance. A manager, if he is to run his business intelligently, has to use economic concepts rather than technical ones. The difference between an economic and technical concept is still not fully appreciated by the business community. The essence of business is the ability and willingness to take a risk, and profits are the legitimate return for risk-taking. Profits are based on relative prices and costs—on economic considerations and not technical ones.

How far does the concept of productivity help the manager to maximize his profits? Productivity ratios can be (and perhaps should be) worked out for all significant factors of production used in any particular process—labour, materials, machinery, floor space and so on. But the ratios themselves are of little value, since they cannot be compared against a standard. A more significant feature is the change and the rate of change in the ratios over time. But when all these ratios and changes in ratios have been worked out, how do they help the manager to maximize his profits? If the manager can legitimately assume that relative prices are unchanged, then an increase in productivity of any factor of production will mean a decline in cost per unit of output. Productivity as a concept is only helpful as a step in calculating changes in costs; and even then it can be misleading since it turns attention away from the real problem confronting management—namely, the provision and use of proper information.

The basic information necessary for taking management decisions is the normal accounting and statistical data, and these should be designed in such a way that they can be used for most, if not all, management decisions. Unfortunately, most accounting data are usually presented in such a form and so late as to be of little value to the manager in taking current decisions or in looking to the future. Accountants have had to concentrate much more on form and presentation of data rather than on the content and on the concepts on which the data are based. A manager, however, is an 'operational economist': all his decisions are basically those connected with economic problems in the sense that they are concerned with relative prices. Any accounting information intended to help management to take the right decisions must be based on economic principles.

A sectional meeting which attracted considerable interest was one concerned with a woman's approach to management. The speaker was Elizabeth Barling (John Lewis Partnership), who suggested that in some civilizations men enjoy much more freedom than women. In Western countries, however, men enjoy considerably less freedom and are inured to considerably more discipline.

Most men have wives and families to support and think about. Most career women either have husbands who have jobs or are unmarried and, economically, have only themselves to think about. Men have to play safer, so far as their jobs are concerned, than women. Women will not stay in jobs they do not enjoy. Men mostly will—if security and perhaps pensions depend on their doing so. Creativity is essentially a product of freedom. Staying in a job that is disliked or playing safe in a job that is disliked are not the conditions in which creativity flourishes. If women are less inured to discipline—and if industry wants their ideas—then industry must recognize that their creativity may depend on conditions of freedom and do what it can to foster those conditions.

It is incompetence in dealings with people that holds British industry back. How to get people to work effectively together? Where to find an incentive that really lasts? How to remove the traditional suspicions and fears that prevent workers from going all out to increase national productivity and their own standard of living? How to turn not just virtues but the weaknesses in human nature to good account in the interest of the firm and of the country? These are the real problems of to-day and women have a part to play in their solution.

The implications of budgetary control for financial research were considered by A. E. Tunley (Harris Lebus Ltd.). The kind of research into the completed budget would raise such questions as:

(1) Is the estimated profit up or down compared with previous years, and is this in keeping with the trend in industry generally and in the particular industry in which the organization operates? Does the profit appear in general to reflect a comparable achievement to that of its chief competitors?

(2) Does the estimated profit in relation to the estimated capital employed show an improvement or a deterioration over previous periods, and do these variations reflect a general trend in the industry or are they peculiar to the organization? If not, are they temporary and a part of a deliberate policy of long-term improvement?

(3) Of equal importance in testing the efficiency of an organization is to see that the rate of profit earned on profits retained in the business is at least equal to the profitability of the original capital—the true test of the growth of a company.

A change in the profitability of capital employed can arise from several causes, and it is desirable to investigate which of these operated. It may be that costs as budgeted have increased, and it is not thought possible to pass this on to customers. It is important to consider why costs have increased and whether the increase is avoidable. Various ratios and indices of measurement will lead to further investigations, such as:

(i) the elements of manufacturing, distribution and selling costs expressed in terms of a suitable unit which eliminates the price element (that is, a productivity unit or a selling unit) to indicate trends by comparisons with previous years.

(ii) comparisons of labour efficiency as projected in the budget compared with past records.

A fall in profitability of capital employed could be due to a slowing down in turnover in capital. A breakdown of the elements of capital employed in relation to volumes of sales should give a lead as to where the slow-down is occurring. The fall in profit in total and in relation to capital employed may be due to a fall in turnover. If, however, the problem has remained intractable, and the shrinkage in turnover seems to be progressive over a long term, it must mean that there is either a developing shrinkage in the market for the company's products or that the company itself is becoming progressively uncompetitive.

If the problem is the former one, then the company must consider some more profitable use of capital.

If the problem seems to be one of competition, the company must discover whether the reason is price—which may be due to: inefficiency in direct cost; too high an overhead burden; an attempt to obtain too high a margin.

All these tests—and others—applied to the trend of an organization's figures in the final budget will indicate how a business is progressing in relation to its own standards. The question still remains whether it is improving its position in relation to its competitors and in relation to industry generally; whether it is better or less than average; whether it is showing sound incipient strengths that could well be exploited. It is difficult to establish these facts unless there is some established method of comparison between firms. These take the form of detailed exchange of cost information on a common costing method or financial ratios.

The part the universities could play in management research was discussed by Prof. N. C. Hunt (University of Edinburgh), who suggested that many apparent personality problems in industry are, in fact, organizational problems. Given that organization, people would react similarly however well trained and well chosen they might be. They create situations in which workers who have been educated to be active, independent adults with real abilities are required to behave more and more like infants—dependent, subordinate and passive—even though they may be well paid for it and well treated. This must tend to frustrations which in turn lead to an increase of aggression and a reduction of efficiency. In this situation managers are asked to do the impossible. Whether they are autocratic or democratic, optimum results are persistently elusive.

Much could be gained by researchers going into businesses without a detailed frame of reference to investigate a particular problem. Free to follow their own devices they might well stumble upon important discoveries which might have been missed had a definite course been set. University researchers must keep themselves free to tackle problems in their own way, however 'practical' these problems may be. The business world would do well to make it possible for them to investigate problems which are not obviously practical and which may seem irrelevant.

Research in management must be a co-operative venture between the universities and the business community. It cannot be undertaken on any scale by business men immersed in the day-to-day problems of management. Neither can it be done by academics confined to laboratories and libraries.

Besides the sectional meetings, twenty-six discussion groups were arranged concerned with subjects varying from management ratios in the small firm to research in labour turnover; from research into industrial markets to ways in which management can be kept informed of scientific development and research findings. The groups led to extensive shaping of experience which should prove to be of considerable value to British industry.

The Conference was also addressed by Dr. A. King, deputy director of the European Productivity Agency, who illustrated the value of research as an investment.

T. H. HAWKINS

OBITUARIES

Sir Ernest Kennaway, F.R.S.

THROUGH the death of Sir Ernest Kennaway, which took place on January 1 (peacefully in his sleep, at St. Bartholomew's Hospital), cancer research in Britain has lost its *doyen*, and experimental pathology one of its greatest figures.

Ernest Laurence Kennaway was born on May 23, 1881, the son of Laurence James Kennaway, of Exeter. As a scholar of New College, Oxford, he took a first-class in the final honours school of natural science in 1903. Proceeding to the Middlesex Hospital with a university scholarship, he graduated B.M., B.Ch., in 1907, and D.M. in 1911. After working for short periods at the Lister Institute and at University College, London, he then successively became demonstrator of physiology at St. Thomas's Hospital (1908), Hulme research student at Brasenose College, Oxford (1909), and demonstrator of physiology at Guy's Hospital (1909–14). In 1911, he was awarded a Radcliffe travelling fellowship by the University of Oxford, and studied at Heidelberg and at Munich. In 1915, he obtained the D.Sc. of the University of London.

He joined the staff of the Cancer Hospital in London as physiological chemist in 1921, and in due course became director of its Research Institute (now the Chester Beatty Research Institute), in succession to Dr. Archibald Leitch; and was also elected professor of experimental pathology in the University of London. He retired from the staff of the Royal Cancer Hospital in 1946, becoming professor emeritus, and continued his researches at St. Bartholomew's Hospital. In a long life he accumulated many honours—the William Julius Mickle fellowship of the University of London, the first award of the Anna Fuller Memorial Prize (jointly), the Garton Prize of the British Empire Cancer Campaign, the Walker Prize of the Royal College of Surgeons of England, the Baly Medal of the Royal College of Physicians of London, the Osler Memorial Medal of the University of Oxford, and an honorary fellowship of New College —among others. He was elected Fellow of the Royal Society in 1934 (and a Royal Medallist in 1941), and of the Royal College of Physicians in 1937, and received the honour of knighthood in 1947.

In the period from about 1910 to 1920, Kennaway was the author of a whole series of papers, on a great diversity of topics, which unmistakably revealed the breadth of his knowledge and interests in chemistry, physiology and pathology, and gave a taste of things to come. Certainly, however, it is upon his massive achievements in the sphere of malignant disease that his name and fame are based and will endure. In the early 'twenties, great efforts were under way to elucidate the nature of the cancer-producing agent in tar and pitch, following the successful induction of cancer through application of coal-tar to the rabbit skin by Yamagiwa and Ichikawa (1915), and in the mouse by Tsutsui (1918). Between 1921 and 1926, Bloch in Zurich had found that the active substance was concentrated in the higher boiling fractions as a neutral compound probably belonging to the class of cyclic hydrocarbons. In 1924–25, Kennaway succeeded in producing carcinogenic tars by the pyrolysis of many organic materials, and by leading acetylene and isoprene with hydrogen through heated tubes. The tars obtained at successively higher temperatures showed an ascending potency, and the results could be explained by assuming that acetylene was a common decomposition product, and that the carcinogenic material was built up from it. In all this work, Kennaway ever acknowledged the value of Berthelot's classical paper of 1866, describing for the first time the production from acetylene of these very kinds of molecule.

We are fortunate, indeed, that he left his own characteristic account of these and later developments (*Brit. Med. J.*, 2, 749; 1955), setting forth their history, and making clear the essential part played by others at the Cancer Hospital—W. V. Mayneord's examination of the fluorescence spectra of the carcinogenic tars, and the discovery of their special qualities (1927); the development of this clue by I. Hieger ;—the discovery that 1 : 2-benzanthracene gave a spectrum similar to that of the carcinogenic mixtures; and J. W. Cook's studies of the benzanthracene homologues. About this time, Clar had just published methods for the synthesis of certain benzanthracene hydrocarbons. These compounds were tested by Kennaway and Hieger (1929–30), who soon observed positive results with 1 : 2 : 5 : 6-dibenzanthracene: this was the first pure compound manifesting pronounced carcinogenic properties, and one cannot forget the satisfaction and modest pride which Kennaway obtained from the fact. The fluorescence spectrum—in Kennaway's words "the single thread that led all through this labyrinth"—was also used in the concentration of the agent from coal-tar pitch, culminating in the isolation of a hydrocarbon which showed the characteristic spectrum and which proved to be highly carcinogenic. Its properties suggested one of the two benzpyrenes, and these were synthesized by J. W. Cook and C. L. Hewett, who were then able to prove the identity of one of the compounds (3 : 4-benzpyrene), and the substance from pitch. All these, and many other results which Kennaway alone inspired, are embodied in numerous papers (many of them classics) in the scientific literature at home and abroad, and, most notably, in a celebrated series which appeared in the *Proceedings of the Royal Society* during 1932–42. What undoubtedly emerged from almost thirty years of brilliant work was a satisfying and indeed beautiful correlation between chemical constitution and biological action, whereby the carcinogenic sub-classes of polynuclear hydrocarbons could clearly be related to the parent substance phenanthrene, in a system suggesting dependence upon certain optimal features of molecular size, shape, substitution and reactivity. But we must not minimize another result—namely, the profound practical influence which was exerted upon the whole of cancer research, and indeed biology at large, from the mere availability of these potent carcinogens, so rendering possible, and catalysing, numerous other investigations, and additions to knowledge, which could not have been attained without them.

No imagination is needed to see how this career demanded a patient sense of purpose over so many years. In certain ways Kennaway possessed a unique combination of qualities—in his intellectual aptitudes, his chemical sympathy and knowledge, and in his unrivalled skill in applying them to physiology and pathology. Apart from his modern scientific bent, he was also a true naturalist, believing greatly in field work and epidemiology. His standards of scientific evidence were rigorous and severe, to the point of austerity. His experimental methods were simple, practical and decisive, and a delight to watch in execution. He was much less interested in hypotheses and explanations, and although his own work had lain almost entirely in the chemistry of carcinogenesis, he remained completely open and free to accept any other mechanism or interpretation—provided only that the facts were ascertained, and not an instant before. Added to all these gifts, he was a master of scientific expression, and of English construction.

We have lost a great discoverer and scientific worthy. Among his personal attributes two things prevailed. First, his profound agnosticism. Secondly, a superb fortitude, which enabled him to triumph over disability, illness and accident, and to continue his researches long after his official retirement and almost to the day of his death. Of course, he had many other interests, and many human concerns which he did not parade and which, contrariwise, he often tried to conceal. It is idle to pretend that Kennaway was easy, or that he could readily apply to ordinary judgments the quality of detachment he brought to his special field. But for how many can anything of the kind be claimed ? Although he could be subjective and quixotic even more than most of us, these foibles were mere additions—often endearing—to the fascination of an already complex human character, and had no real bearing on the solid worth of his permanent achievement.

No appreciation could be complete which failed to refer to a factor at all times apparent to those who worked with him—the part played by Lady Kennaway in every aspect of his life and contribution. Not in any small measure due to his helpmeet, he wrote a vast chapter in cancer research and chemical pathology, which nothing can diminish, or take away.

A. Haddow

Dr. A. J. Ewins, F.R.S.

Dr. Arthur James Ewins died after a long illness on December 24, aged seventy-five. He will long be remembered for his discovery of several important chemotherapeutic remedies.

Ewins was born in 1882 at Norwood, the son of Joseph Ewins, who was a signalman on the London and South-Eastern Railway. A scholarship took him to Alleyn's School, Dulwich. Leaving at the age of seventeen, he obtained a position as technician at the Wellcome Laboratories, Herne Hill, working under Dr. (later Prof.) G. Barger. By evening studies at Chelsea Polytechnic, he graduated with honours in 1906, and was promoted to the staff of the Wellcome Laboratories. Soon he began to co-operate with Dr. (later Sir) Henry Dale in work on acetylcholine, other choline esters, and the ergot alkaloids, and this formed the basis of a long and valued friendship between them. When Dale entered the service of the Medical Research Committee (later Council) in 1914, Ewins did the same, and worked with him in the production of 'Salvarsan' and other drugs formerly made in Germany and by then no longer available. Early in 1917 he was offered an attractive appointment with May and Baker, Ltd., which he accepted; and he continued with this firm for the rest of his scientific life, becoming the head of its chemical research department and director of research.

Ewins's main interest was in chemotherapy. After much work on the organic arsenicals, he turned his attention to other fields. In the middle 1930's Dr. E. M. Lourie and Prof. Warrington Yorke, of Liverpool, had discovered that synthalin was very active in killing trypanosomes *in vitro*. Following development work by the late Dr. Harold King at the National Institute for Medical Research, Ewins took up this lead and synthesized a long series of diamidine compounds, of which the most active, pentamidine, has proved of great value in combating sleeping sickness in Africa. One intramuscular injection is enough to protect a man against this infection for six months, and this procedure has been applied to millions of people in tropical Africa to safeguard them against this dangerous disease. Another member of the same series—phenamidine—is widely used for curing babesiasis (redwater) of cattle and dogs. These drugs are also active against kala-azar.

The work for which Ewins is best known was his discovery of the famous '*M* & *B* 693', or sulphapyridine as it was later named. After prontosil had been prepared by Domagk and Mietsch in 1933 as a cure for streptococcal infections, the French workers, Trefouel and Bovet, showed that the antibacterial activity resided in the simple structure—*p*-aminobenzene sulphonamide, or sulphanilamide. The early attempts to obtain greater and wider activity by modification of this structure were not very successful until in 1937 Ewins and Phillips inserted a pyridine group in the sulphonamide radical. This compound was tested by Sir Lionel Whitby and found to be very active in curing mice experimentally infected with pneumococci. The new compound was quickly applied to human infections and proved to be brilliantly successful, and for the first time in medical history lobar pneumonia could be cured by a simple drug. Later, sulphapyridine was supplanted by other more active and less toxic compounds (including sulphathiazole synthesized by Ewins and Newbery), but the inspiration of its discovery will long be remembered. In 1943, Ewins was elected to the Royal Society. He continued to direct the research organization which he had built up until his retirement in March 1952.

Ewins was a simple and modest man, but he knew his own mind, and once he had made a decision he persevered with determination. He was well liked and well respected. Besides his scientific work, his chief pleasures were working in his garden, reading and motoring. He leaves a son and a daughter.

NEWS and VIEWS

The United Kingdom Atomic Energy Authority

MR. W. R. J. COOK, deputy director of the Atomic Weapons Research Establishment, Aldermaston, has been made a full-time member of the Atomic Energy Authority. This new appointment makes it possible to progress towards certain alterations in the structure of the Authority. Three full-time members of the Authority have hitherto each had three types of responsibility. First, they have had executive control of one or more of the Authority's establishments. Second, they have been responsible for formulating policy on, and for broad oversight of, the subjects constituting their own special fields (research, production and engineering, and weapons). Third, they have had to join with their colleagues in considering and deciding jointly on the general policies to be pursued by the Authority. The purpose of the alterations which are being made is to free these members from their executive duties, and thus enable them to devote more time to their other responsibilities. Sir John Cockcroft, who has since the setting up of the Authority held the posts of member for scientific research and director of the Atomic Energy Research Establishment, Harwell, will be succeeded in the latter post by Dr. B. F. J. Schonland (the present deputy director).

Mr. Cook will be responsible at Board-level for policy questions concerning the Authority's production factories and the engineering aspects of the Authority's work. Since Sir Leonard Owen was appointed managing director of the Industrial Group in September 1957, he has had executive charge of the establishments in that Group. Sir William Penney will continue to be member for weapons research and development and, pending the appointment of a new director of the Atomic Weapons Research Establishment, he will continue to hold that post also. The duties of Sir Donald Perrott, member for finance and administration, and of Mr. W. Strath, member for external relations and commercial policy, are unchanged. Mr. Cook and Dr. Schonland will take up their new appointments on February 17.

National Research Council of Canada:
Dr. J. B. Collip, C.B.E., F.R.S.

THE retirement is announced of Dr. J. B. Collip from the directorship of the Division of Medical Research of the National Research Council of Canada. He has held this appointment since 1947 when the new Division of Medical Research superseded the old Advisory Committee on Medical Research, of which Dr. Collip had also been chairman since 1941. Dr. Collip, of course, is best known for his work in purifying the early preparations of insulin and thus playing a leading part in making this hormone available for general clinical use. Dr.

Collip, however, has many other claims to the respect and admiration of the scientific world. His work with extracts of pancreas seemed to whet his appetite for hormones, and he next attacked the parathyroid gland which at that time was something of a mystery as an endocrine organ, and he succeeded where others had failed in obtaining a reproducibly active preparation. Next he worked on the newly recognized hormones of the anterior pituitary lobe, gonadotrophin, thyrotrophin and adrenocorticotrophic hormone, with a brief but productive excursion to the placenta. From the latter organ he prepared both œstrogenic and gonadotrophic extracts upon which he worked for some time in 1930 at the National Institute for Medical Research in London. Since the beginning of the Second World War his time has been taken up very largely by organizational work, partly in connexion with his appointment to the National Research Council but also as dean of medicine at the University of Western Ontario, a position which he still holds. No one meeting Dr. Collip could fail to be aware of his active and forceful mind or of the keen intelligence with which he dissects the various parts of a problem, and it is fitting at this moment to pay tribute to his services to medical science generally and to the National Research Council of Canada in particular.

Prof. R. F. Farquharson, M.B.E.

The recent appointment of Prof. Ray Fletcher Farquharson as vice-president (medical) of the National Research Council of Canada, in succession to Dr. J. B. Collip, is one which is regarded with much pleasure and satisfaction by physicians and scientists alike throughout Canada. Born in Claude, Ontario, Dr. Farquharson graduated from the University of Toronto Medical School in 1922, and after six additional years of postgraduate training in internal medicine in Toronto and in Boston he was appointed to the staff of the University of Toronto as demonstrator in medicine and began to practise as a medical consultant. In both his university and professional work he was eminently successful and he rose rapidly in academic rank. In 1935 he was appointed assistant professor of medicine in charge of therapeutics and in 1947 he succeeded Prof. Duncan Graham as the Sir John and Lady Eaton professor of medicine and head of the Department of Medicine in the University of Toronto and as physician-in-chief to the Toronto General Hospital—posts which he still holds. During the Second World War he was on active service with the Canadian Armed Forces, serving with the rank of wing-commander as consultant in medicine to the Royal Canadian Air Force, and from 1948 until 1951 he was a member of the Defence Research Board of Canada. He is a Charter Fellow of the Royal College of Physicians and Surgeons of Canada and, in addition to serving on its Council for many years, was president of the College during 1945–47. He has been associated with the National Research Council of Canada since 1945, first as a member of the Division of Medical Research and then as a full member of Council. With his recent appointment as vice-president (medical) he will be in charge of all the medical activities of the Council. In spite of his many other activities, he has found time to carry out and publish an impressive amount of clinical research; his work on calcium metabolism, pernicious anæmia, Simmonds' disease and anorexia nervosa is particularly well known. Widely recognized throughout Great Britain and the United States as well as in his own country as an outstanding physician, a first-rate investigator, an enthusiastic teacher and an able administrator, and held in the highest esteem and affection by his colleagues and patients, he brings to his new post a fund of ability and experience which augurs well for medical research in Canada.

Applied Mathematics in Durham: Prof. K. Stewartson

Dr. Keith Stewartson, reader in applied mathematics in the University of Bristol, has been elected to the newly created chair of applied mathematics in the University of Durham. Dr. Stewartson was a Wrangler in Part 2 of the Mathematical Tripos in Cambridge in 1944 and then had his studies interrupted by two years national service in the Ministry of Supply. He returned to Cambridge in 1946 to read for Part 3 of the Mathematical Tripos, in which he gained a mark of distinction in the following year and the Mayhew Prize. He then took up research in fluid mechanics and was awarded the Rayleigh Prize in 1949 for an essay on supersonic flow. He took his Ph.D. in 1949 and was at the same time appointed lecturer in the University of Bristol. He became reader in 1954 on his return from a year's leave of absence spent as a research fellow at the California Institute of Technology.

Dr. Stewartson's contributions to fluid mechanics have come under the headings of supersonic flow, magneto-hydrodynamics, boundary layer theory and rotating fluids, and of these perhaps the last two are the more important. In earlier work on boundary layers he showed (as did Illingworth simultaneously) that under certain special, but not unrepresentative, conditions it is possible to correlate the flow in compressible boundary layers, and he has also concerned himself with the phenomenon of separation, both shock-induced and in incompressible flow. His work on the mechanics of rotating fluids has comprised contributions to inviscid theory in such problems as the motion of a sphere along the axis of a rotating fluid, and to viscous theory in such problems as the flow between two rotating coaxial disks and the discussion of almost solid rotations.

University of Durham Computing Laboratory

The Computing Laboratory of the University of Durham was officially opened on January 21 by Sir George Thomson, who spoke of the wide field of application of electronic computers, not only as an aid in scientific calculation, but also in the study of the humanities by the analysis of literary style. The Laboratory has recently installed the Ferranti 'Pegasus' computer 'Ferdinand' (FERranti DIgital Numerical Analyser Newcastle and Durham). The cost of the machine has been met by a grant from the University Grants Committee and by contributions from firms in the north-east of England. 'Ferdinand' was demonstrated to representatives of many firms after the official opening and naming ceremonies. The machine will be used for research work by university departments and will also be available for hire by industrial and commercial concerns.

Royal Photographic Society Award

The Royal Photographic Society of Great Britain has awarded its Silver Progress Medal for 1957, the Society's highest award, to Dr. Edwin H. Land, president of the Polaroid Corporation, Cambridge, Massachusetts, for his outstanding contributions towards the development of synthetic polarizers for light (for example, 'Polaroid'); of stereoscopic photography using polarized light one-step photography ('Land' camera); of the ultra-violet colour-translation microscope; and of the use of plastics and colloids in optics. Honorary Fellowship of the Royal Photographic Society has been conferred upon Dr. John I. Crabtree (Research Laboratories, Eastman Kodak Co.), who has been responsible for major developments in the practice of processing black-and-white still- and motion-pictures; and also upon Dr. E. H. Land.

Pooling Scientific Resources in the Western World

In a written answer given on January 21 in the House of Commons to a question regarding the Government's policy as to the pooling of scientific knowledge in the interests of international peace and co-operation, Mr. R. A. Butler re-affirmed that the Government is in favour of pooling scientific resources. He added that discussions with other members of the North Atlantic Treaty Organization and the Organization for European Economic Co-operation are proceeding with the view of promoting this continuing co-operation. The most important recent step towards scientific co-operation in the government field has been the joint decision of the North Atlantic Treaty Organization to establish a Science Committee and to appoint a Science Adviser to the Secretary-General.

Technical and Technological Education in Scotland

Replying on January 21 to a question in the House of Commons regarding the expansion of scientific and technological education in Scotland, the Joint Under-Secretary of State for Scotland, Mr. N. Macpherson, said that projects to the value of £7,300,000 have already been approved by the Secretary of State. He added that further projects to the value of £1,200,000 are being considered and it is expected to receive shortly a scheme for the remaining £1,500,000. Every opportunity is being taken by means of conferences and other forms of publicity to encourage employers and young workers to make full use of the facilities available.

National Science Foundation Grants for Research Reactors

Two major grants for research reactors are to be made by the National Science Foundation, namely, a 300,000 dollar grant to the State College of Washington, at Pullman; and a 150,000 dollar grant to the University of Virginia, at Charlottesville. The reactor facility to be constructed at the State College of Washington will be a swimming-pool type, heterogeneous reactor using enriched fuel elements and moderated by water. The reactor will have twelve beam ports, a thermal column, and at a power level of 100 kW. will provide a core flux of about 10^{12} neutrons/cm.^{2}/sec. The project is under the direction of Harold W. Dodgen, of the Department of Chemistry. The proposed facility is near seven other institutions of higher learning and is expected to contribute to the development of a regional programme in reactor research and training in nuclear technology. The project is also being assisted by the U.S. Atomic Energy Commission. The research reactor at the University of Virginia will also be of a swimming-pool type. The School of Engineering is participating in the design and construction of the reactor, thereby making possible appreciable savings in cost. The project is under the direction of Lawrence R. Quarles, dean of the School of Engineering. The staff has been actively planning research with nuclear radiation in the fields of biology, chemistry, engineering, medicine and physics. Nuclear fuel for both reactors will be provided by the United States Atomic Energy Commission.

The Midwestern Universities Research Association

The National Science Foundation has awarded a grant of 160,000 dollars to the Midwestern Universities Research Association, Madison, Wisconsin, for the support of basic research entitled "High Energy Accelerator Studies". The research is under the direction of Keith R. Symon, of the University of Wisconsin. Since 1953, scientists of the Association have been investigating methods of accelerating particles to energies of billions of electron volts. They discovered that a machine based on the principle of a fixed-field-alternating gradient was feasible, and a model was built to demonstrate this principle. The basic theory of accelerators was also developed to a point in advance of anything that had thus far been achieved. The work was facilitated by the use of high-speed computing machines, which were used to carry out analyses not otherwise possible. With the new grant, which supplements funds received from the U.S. Atomic Energy Commission, the Midwestern Universities Research Association expects to continue those studies of new ways of producing high-energy collisions involving beams of protons. It will continue to investigate the orbits and accelerating field configurations for the intersecting-beam method of producing 'effective' energies of tens of billions of electron volts. Theoretical studies will be made of the temporary 'stacking' of orbiting particles. Because the feasibility of an intersecting-beam accelerator depends on the intensity in the beam, it is planned to build a new pilot model to test the theoretical calculations that have been made on beam intensity. The model will operate at 50 million eV. and be so built that counter-circulating beams of particles can be studied. The radiation effects and the spurious interaction of these circulating beams will also be investigated.

History of Libraries

In his inaugural lecture, "The Golden Chain: a Study in the History of Libraries", at University College, London, on November 21, Prof. R. Irwin suggested that the history of libraries is essentially concerned with the conquest of space and time by the art of recording communications, and involves not only the history of scholarship in its narrower sense, but also of human civilization, culture and literacy. Moreover, he pointed out that the genealogy of scholarship and letters is as complex as any family tree. Books have their ancestry and descendants, and a book is a kind of reincarnation of the author that gradually gathers to itself an independent life of its own. An author's literary offspring are always the result of a marriage between his own mind and the communicated experience of other minds, in the main received through the medium of books, so that the conception and birth of the new book commonly occurs in the author's library or, for a scientist, in his laboratory. Prof. Irwin suggested that a library can be defined as a community in which reader and writer meet, to which both contribute something of value, mutually forging the links of the chain as it passes from mind to mind and from generation to generation. At the centre of this community is the librarian, with his two main duties of preserving for future readers the books in his care and of caring for the needs of every member of that community and for the chain of recorded tradition which is continually being corrected, strengthened, extended and passed onwards.

Indian Ephemeris and Nautical Almanack (1958)

THE publication of the first issue of the Indian Ephemeris and Nautical Almanack (pp. xviii+392. Delhi: Manager of Publications, 1957. Rs. 12) marks an important step in the plans for the development of astronomical studies in India. The preparation of such a work was first recommended by the Planning Committee for the development of astronomy and astrophysics set up in 1945 under the chairmanship of the late Prof. M. Saha. In 1952, the Government of India appointed a Calendar Reform Committee with the object of unifying the diverse indigenous calendars (see *Nature*, 178, 402; 1956). This Committee recommended that an Indian Ephemeris and Nautical Almanac for each year should be compiled and issued by the Government. The work was started by the Council of Scientific and Industrial Research under the Ministry of Natural Resources and Scientific Research, but it has now been taken over by the Indian Meteorological Department under the Ministry of Communications, and a Nautical Almanack Section has been set up at the Regional Meteorological Section, Alipore, Calcutta. At the end there is a section on Indian astronomy, added in accordance with the recommendation of the Calendar Reform Committee. The work of compiling and publishing the present issue has been under the supervision of Sri N. C. Lahiri, who has also been responsible for the introduction, dealing with the history and development of astronomy in India from about 1350 B.C.

Vacuum Drying Oven

THE Gardiner precision vacuum oven, developed by S. D. Gardiner in the laboratories of Tate and Lyle for the determination of the loss in weight on heating sugar syrups and molasses, is now in production by Griffin and George, Ltd., Ealing Road, Alperton, Wembley, Middlesex, from whom particulars of it may be obtained. In this oven the sample is taken into solution and distributed over aluminium powder. It is then heated in a vacuum while a current of dry air or inert gas is taken over its surface. Suitable arrangements for heating the specimen are incorporated. The oven will be suitable for use with various types of materials, including those of a labile nature.

Developmental Potentialities of Fern Leaf Primordia

E. G. CUTTER (*Annals of Botany*, N.S., 21, 343; 1957) has noted that when young visible primordia, which are not yet determined as leaves, on inactive apices of *Dryopteris aristata* are isolated by four shallow incisions, they undergo regression and disappear; but if the adaxial incision is afterwards deepened, some of the primordia are stimulated into a renewal of growth. About three-quarters of this number developed as buds, the rest as leaves, some of which were of radial symmetry; others became dorsiventral, but were sometimes abnormally orientated. Such primordia usually underwent a phase of radial symmetry during development. Subsequent deepening of the abaxial or radial shallow incisions was usually without effect. In a discussion of the problems of leaf determination, symmetry and orientation, it is suggested that, in specimens where the isolated primordia developed as leaves, the experimental treatments have merely fortuitously reproduced the regulative effects normally exercised by the shoot apex and adjacent primordia. There may be specific relationships between the size and growth capacity of the primordium and that of the shoot apex on which it is formed. Three phases in the development of a leaf primordium of this species can now be distinguished: inception as a growth centre, determination as a foliar organ of limited growth, and development as an organ of dorsiventral symmetry. Under normal growth conditions, radial leaf development is never observed, but when growth is unusually slow it may become manifest. In other species the temporal relationships between these phases of development may differ, so that they cannot be differentiated by experimental means.

Second International Symposium on Freezing and Drying

THE Institute of Biology is arranging a symposium on freezing and drying to discuss progress in this field since the first symposium held in 1951. The meeting is to be held in the Beveridge Hall, Senate House, London, W.C.1, on April 1 and 2. Some twenty speakers, including workers from France, Japan, Kenya, the United States and the U.S.S.R., have accepted invitations. The symposium will be open to the public. Further information can be obtained from the Institute of Biology, 41 Queen's Gate, London, S.W.7.

"Structure of Brain Ganglioside"

WITH reference to the communication under this title by Dr. Samuel Bogoch published in *Nature* of July 27 (180, 197; 1957), Dr. J. Folch-Pi, director of scientific research, McLean Hospital (Harvard Medical School), Waverley, Mass., states that Dr. Bogoch should have mentioned that most of this work was carried out at the McLean Hospital Laboratories, and that it was supported by the American Cancer Society (Grant *BCH*-11 *et seq.*).

University News: London

THE British Steel Producers' Conference and the British Constructional Steelwork Association have offered £6,000 a year to the Imperial College of Science and Technology, London, for the establishment of a readership in structural steelwork in the Department of Civil Engineering and the provision of a number of bursaries for postgraduate study in that subject.

Nottingham

THE title of reader in applied mathematics has been conferred on Mr. John Edward Adkins.

The Night Sky in February

FULL moon occurs on Feb. 4d. 08h. 05m U.T., and new moon on February 18d. 15h. 38m. The following conjunctions with the Moon take place: Feb. 9d. 14h., Jupiter 2° N.; Feb. 13d. 09h., Saturn 2° S.;

Feb. 14d. 12h., Mars 5° S. In addition to these conjunctions with the Moon, Mercury is in conjunction with Venus on Feb. 7d. 07h., Mercury being 9·6° S. Mercury is too close to the Sun for normal observation. Venus is a morning star, visible low in the south-east before sunrise. It rises at 6h. 25m. and 4h. 55m. on February 15 and 28, respectively. Mars rises at 5h. 20m., 5h. 10m. and 4h. 55m. at the beginning, middle and end of the month, respectively; it is visible in the south-east before sunrise. Jupiter rises at 0h. 10m., 23h. 15m. and 22h. 25m. on February 1, 15 and 28, respectively; it is east of Spica, and is stationary on February 16. The stellar magnitude of Jupiter is − 1·8, its distance from the Earth on February 15 being 460 million miles. Saturn rises at 4h. 45m., 3h. 55m. and 3h. 10m. at the beginning, middle and end of the month, respectively; it is near θ Ophiuchi. It has a stellar magnitude of + 0·8 and a distance of 980 million miles from the Earth on February 15. There are no occultations of stars brighter than magnitude 6 visible at Greenwich.

Announcements

Mr. R. R. Blackwood, general manager of the Dunlop Rubber Co. of Australia, formerly professor of mechanical engineering in the University of Melbourne, has been appointed chairman of the interim Council of the new University of Victoria. It is also expected that he will be the first chancellor of the University when it becomes established (see p. 300 of this issue).

Dr. J. A. Fraser Roberts, director of the Medical Research Council Clinical Genetics Research Unit, Institute of Child Health, The Hospital for Sick Children, Great Ormond Street, London, W.C.1, has been elected president of the Royal Anthropological Institute for the years 1957–59.

Dr. M. C. R. Symons, lecturer in chemistry in the University of Southampton, has been appointed visiting associate professor in the Department of Chemistry at the University of British Columbia for the period January 1–June 30.

The following appointments in the Ontario Research Foundation have been announced: Dr. A. E. R. Westman to be director of research of the Foundation, Dr. H. B. Marshall to be director, Department of Chemistry, and Dr. S. G. Reid to be an assistant director in that Department.

The Fifteenth International Horticultural Congress will be held in Nice during April 11–18, under the presidency of M. Henri Queuille. The theme will be "Science in the Service of Horticultural Techniques". Further information can be obtained from M. le Secrétaire général du XV^{e} Congrès International d'Horticulture, 84 rue de Grenelle, Paris 7^{e}.

The fifth Easter School in Agricultural Science will be a symposium and colloquium on "The Nutrition of the Legumes". It will be held at the University of Nottingham School of Agriculture, Sutton Bonington, near Loughborough, Leicestershire, during April 14–17. Further information can be obtained from the conference secretary, Mr. E. A. N. Greenwood, at the above address.

The first international symposium organized by the International Collegium for Neuro-Psychopharmacology will be held in Rome during September 9–12. In addition to organized symposia, there will be certain sessions devoted to original communications. Those interested in presenting papers should send a 250-word abstract before March 31 to Dr. P. B. Bradley, Department of Experimental Psychiatry, The Medical School, Birmingham 15, from whom further particulars may be obtained.

The Radiation Research Visiting Club is holding a meeting in Cambridge on March 20 and 21 on the theme of the action of high-energy radiation on solids. Further details may be obtained from Dr. A. J. Swallow, Tube Investments Research Laboratories, Hinxton Hall, nr. Saffron Walden, Essex.

The South-Eastern Union of Scientific Societies is organizing a conference on conserving wild life and amenities in the south-east of England, to be held at the Zoological Society of London, Regent's Park, N.W., on April 12, under the chairmanship of the Earl of Cranbrook. Each member society is being invited to nominate two delegates to attend the discussions, which, it is hoped, will lead to the formation of Naturalists' Trusts for each county represented.

The second symposium of the Reticuloendothelial Society (New England Institute for Medical Research, Ridgefield, Connecticut) will be held in Rapallo, during August 29–31. It is intended to discuss the subject under three main headings—the reticuloendothelial system and steroids; the reticuloendothelial system and immunity, including antibody immunity and properdin, and tumour immunity; and the reticuloendothelial system and radiation. As in the first symposium, which was held in France at Gif-sur-Yvette in 1956, attendance at the symposium will be limited. Proposed titles of papers from intending participants should be sent, accompanied by a brief summary in English, before March 15, to Dr. Alberto Marmont, Clinica Medica Universitaria, Viale Benedetto XV, Genoa, Italy, to whom inquiries may be addressed.

The Medical Research Council states that in future all requests for compounds in the Steroid Reference Collection should be addressed to Dr. W. Klyne at the Postgraduate Medical School, Ducane Road, London, W.12, and not to the National Institute for Medical Research at Mill Hill. As a result of generous gifts from two industrial firms, larger supplies of œstriol and 16-epi-œstriol (Organon Laboratories) and very limited supplies of racemic aldosterone (Ciba AG, Basel) are now available; these materials are intended for chemical reference purposes, and not for clinical work.

The authors of the first article on "Controlled Release of Thermonuclear Energy", entitled "Production of High Temperatures and Nuclear Reactions in a Gas Discharge" (*Nature*, January 25, p. 217), wish to add the following acknowledgments: (1) investigations leading up to the present results have been constantly encouraged and supported by Sir John Cockcroft, Sir George Thomson and the late Lord Cherwell; (2) invaluable assistance has been given by their colleagues at Harwell and at the Research Laboratory of the Associated Electrical Industries, Ltd., Aldermaston; (3) the erection and maintenance of ZETA has been under the control of J. T. D. Mitchell, of the Engineering Division.

TECHNICAL EDUCATION IN THE U.S.S.R.

AN impressive account indicating the importance attached to technical education in the Soviet Union has been given by C. E. Simmonds in a publication of the Society for Cultural Relations with the U.S.S.R.*.

Compared with a total of 200,000 in Russia in 1913, it is claimed that there are now more than 5 million specialists with a higher or secondary education; about 280,000 specialists with higher education qualified in 1955 and entered various branches of the national economy. Each year about 60,000 'professional engineers' and 70,000 lower grade engineers are being produced; to support their activities the aim is to train two, four or more technicians with secondary schooling for every college-trained specialist. The U.S.S.R. has some 3,000 scientific research institutes, experimental stations and laboratories, and more than 900 institutions of higher education. It has 4,000 technical and other specialized secondary schools.

The system is in many ways simpler than that to be found in Britain, where qualifications depend on State examinations or the requirements of the City and Guilds of London Institute, the specialized professional institutes, the trade unions and industry itself. In the Soviet Union the minimum educational period provided is the seven-year school (seven to fourteen); ten-year secondary education (seven to seventeen) is now established in the large towns, and is to become universal by 1960. Secondary qualifications can also be gained in specialized secondary schools, or *tekhnikums*, which also train secondary school leavers as technicians, or at evening classes. Each trade has its nationally-determined 'technical minimum' and a range of grades of skill with corresponding rates of pay; there is thus a constant incentive to study.

Many workers study in the evening after work; others attend full-time short courses of training or re-training, others (up to the age of thirty-five) win places in the higher technical institutes. The Labour Reserve Ministry has a complex network of schools, and courses for training skilled workers are being increasingly used in factories where automatic processes have been introduced. The Moscow automatic ball-bearing factory is described as "the most advanced production unit of its kind in the world". It turns out 900,000 ball-races and 600,000 roller bearings a year, with a total staff of 178 divided between two shifts. It took six months to design this factory and eighteen months to build it. Some 2,000 or 3,000 designers, including many from centralized research and development agencies, were involved in its planning. The experimental Research Institute for Metal Cutting Machines in Moscow has a staff of more than a thousand scientific workers. The Ordjonikidze machine tool factory has 400 designers and draughtsmen. One Moscow factory employing 4,000 workers has more than forty full-time teachers in its own technical school. The Red Proletariat Works, in Moscow, turns out small universal lathes at the rate of 12,000 a year, using only 1,000 workers. This lathe line took eighteen months to design and build.

To produce a sufficiency of scientists and technologists, Soviet educationists insist that technical education must be broadly based. The aim of the ten-year school is to turn out boys and girls, with a certificate including Russian language and literature (in addition to the native language in the non-Russian Republics) as well as mathematics and physics as compulsory subjects (the standard of the certificate is rather above that of the General Certificate of Education, Ordinary Level), with a good knowledge of basic scientific principles and some conception of their application in industry and agriculture, with practical experience of tools and machines, and, above all, with an interest in the world around them and a willingness to use their hands and brain creatively and adapt themselves quickly to whatever job they choose on leaving school.

The new syllabuses adopted in the past few years include practical handwork and nature study in the first four classes. The course is the same for all pupils, girls and boys, without selection or streaming. The children are encouraged to link up all the subjects they study with what is going on in the community to which they belong, the industrial and agricultural processes, the local climate and geography. In classes 5–7 there are two periods of wood and metal work per week. Practical work in agriculture (linked with biology studies) and electrical technology (linked with physics) also begins at this stage. The main elements of electro-magnetism and its practical application are taught in class 7. Practical work in electro-technology begins in class 7, and continues in the next three classes. Pupils learn how to wire up simple circuits and later they deal with complex apparatus like meters and dynamos. In class 8 engineering and machine study is introduced as the third practical subject, with two periods a week allotted. The work involves theoretical and practical study of various tools and mechanisms, such as parts of cranes, lathes, drills and jacks. The pupils' knowledge is gradually built up from understanding the principles and functions of the parts, to grasping the working of complex machines such as the car and the tractor, which is a main feature in the ninth-year syllabus. Visits to factories, and periods of practical work at some enterprises, are an integral part of school work, more especially if the school has a factory acting as patron, helping with the supply of equipment, lecturers and workshop instructors. The visits take the form of excursions carefully planned and followed up. At some schools, pupils from upper forms go to work at a factory once a week during school time. They work under careful supervision in machine-repair shops, electrical laboratories and tool-rooms.

Simmonds's paper also contains an account of the Labour Reserve Scheme for training skilled workers which was set up in 1940; between 1946 and 1954 more than 5 million skilled workers were trained in a variety of trades in the Labour Reserves Schools.

---

* Technical Education in the U.S.S.R. By C. E. Simmonds. Pp. 36. (London: Society for Cultural Relations with the U.S.S.R., 1957.) 2*s*. 6*d*.

With the extension of ten-year schooling, it was decided, in 1954, to open a new type of two-year technical college, called a *tekhnicheskoye uchilishche*, intended for entrants who had already completed the ten-year school. Two hundred and sixty-one were opened in 1954, and by 1956 the number had grown to four hundred and forty, spread throughout the U.S.S.R. They are designed to train workers and junior technicians for highly skilled and responsible work, to take charge of machinery in rolling mills and mines, or to control automated processes and operate measuring instruments. Steam and diesel engineers, electricians and laboratory workers are being trained for agriculture. Entrance is open to young men and women from the ages of seventeen to twenty-five, local people being given preference in any given area.

Besides the products of the Labour Reserve Colleges, the aim of the sixth Five Year Plan (1956–1960) is to supply 550,000 skilled workers with secondary education from the new two-year technical colleges. The trade and railway schools will train 520,000 workers, the mining and building schools 1,180,000, and the agricultural mechanization schools 1,090,000. New schools are to be developed in Siberia, and more than a thousand million roubles are to be allocated by the Labour Reserve Organization for new schools, buildings, workshops and hostels. The schools vary from excellent to poor, the shortage of teachers and instructors, text-books, equipment and visual aids being still acute. Criticisms are made that the two-year course at the new technical colleges is not long enough, that syllabuses are overcrowded, that on-the-job training needs radical overhauling, students being often used as a reserve of extra workers.

In 1956, 1,961,000 students, internal and external, at 3,757 secondary technical and vocational schools were under the jurisdiction of various ministries. These are distinct from the general schools; their status is higher than that of the Labour Reserve Colleges, but not so high as that of a university or institute. Successful completion of the *tekhnikum* course qualifies the student to apply for entrance to higher establishments. A large number of these *tekhnikums* train skilled workers, junior technicians and supervisory staff for agriculture, engineering, mining, building, transport, but the range is very wide and includes nursing, book-keeping and commerce, finance and credit, various branches of light industry, and one special course for theatre technicians, attached to the Moscow Arts Theatre. One special type of industrial *tekhnikum* trains skilled workers as instructors in the Labour Reserve Schools. At present more than a million technicians and specialists with secondary qualifications are working in industry and agriculture. The sixth Five-Year Plan estimates that more than two and a half million students will complete these secondary technical courses.

The *tekhnikums* are staffed partly by specialist teachers from the universities and institutes, and partly by craftsmen-instructors, full- or part-time, from industry. Successful *tekhnikum* students are expected to go straight into fairly responsible jobs, not usually as craftsmen but as team-leaders, technical and laboratory assistants and assistant supervisors. In agriculture they are expected to take charge of field-work teams or sectors of farm economy. There are already three candidates for each full-time place in a *tekhnikum*; the aim is to expand the intake to double or treble the present figure.

Higher technical education in the Soviet Union includes not only all faculties of all universities but also every kind of specialized institute; it is difficult to give accurate figures for those who graduate from universities or from institutes.

While Soviet universities train science graduates, there are no university faculties for engineering or technology as such. The difference in function of universities and higher technical institutes is well expressed in the report of the British engineers who visited the U.S.S.R. in 1956. "The thirty-three universities do not offer courses in technology, and they do not contribute directly to the education and training of engineers. . . . But the universities offer courses in physics, a great deal of which is applied to engineering, and this brings them into touch with the developing branches of engineering. Physicists and mathematicians from the universities provide some of the teaching force in the institutes, and some of them are employed by industry in application work."

Students at all higher educational establishments in 1956 numbered 1,867,000, an increase of more than 100 per cent since 1941. There are now more than 900 higher educational establishments in the U.S.S.R., including thirty-three universities, and the teaching staff at these establishments is to-day more than 100,000. With its new building for the science faculties, opened in 1953, the University of Moscow has more than 18,000 students, including a number from outside the Soviet Union. In 1946, most technical colleges were brought together under the U.S.S.R. Ministry of Higher Education, instead of being under the jurisdiction of various ministries.

The age limits for admission to higher education institutions are seventeen to thirty-five but there is no age-limit for external (correspondence) students.

After graduation, the State Planning Committee of the U.S.S.R. Council of ministers allocates the year's graduates to the different ministries in accordance with the national economic plan. Posts are allocated by a State Commission which takes into account the wishes and inclinations of the student. Volunteers for work in the central eastern and northern regions are encouraged by appeals to patriotism and the pioneering spirit and also by financial inducements of 10–100 per cent additions to normal wage-rates.

Research work often begins during the undergraduate course and many students are responsible for innovations and inventions. At the Bauman Technical College in Moscow, more than 700 students were engaged in research in 1950 and fifty received certificates for their inventions. The Scientific Society of the University of Moscow has 2,200 student members who conduct research. A number of honours students proceed to postgraduate research for three years, after which they take examinations and present a thesis for the degree of Candidate of Science. The titles of successful theses are published in the specialized journals every year. In 1952, 25,000 postgraduate students were being trained at higher educational establishments and research institutes.

The system of studying as external students, by correspondence or at evening classes, is widespread and forms an integral part of the higher education network. There are twenty-two higher educational correspondence institutions with a large number of branches, and 393 correspondence and 211 evening departments. More than half a million men and women are studying by this method. Correspondence students have short periods of practical work, lectures and examinations each year.

RADIOISOTOPES AND GLASS

A SYMPOSIUM on the subject "Radioisotopes and Glass" was held by the Society of Glass Technology at the Department of Glass Technology of the University of Sheffield on November 27. Dr. W. M. Hampton was chairman of the morning session, followed by the president of the Society, Mr. C. E. Ramsden, who took the chair in the afternoon.

In an introductory lecture, Mr. J. L. Putman (Atomic Energy Research Establishment, Harwell) directed attention to the dual nature of the discussions, in dealing with both the services which radioactive techniques can offer to the glass industry and the demands which the handling and measurement of radioactive materials make upon glass. He mentioned the use of glass for containers and remote-control manipulative equipment for use with radioactive solutions, the use of lead glass as a transparent screening material for operations with high gamma-ray intensities and the use of discoloration as an index of high gamma-ray doses.

Following a brief review of the nature and properties of radioisotopes, Mr. Putman indicated the main ways in which these materials could be used, as radioactive tracers in solid, liquid or gaseous form, as sources of radiation in non-contacting thickness and density gauges, and as dissipators of unwanted electrostatic charges on insulators. A particular note was made of the special role of glass in the construction of Geiger counters and other radiation detectors.

Mr. E. W. Jones (Isotope Developments, Ltd.) spoke on "Glass Level Measurement in Furnaces". After a brief review of orthodox measurements of glass level, he pointed out the advantages of a radioactive system which does not require access to the inside of the containing vessel.

He referred to an early French design using radium as the source, and described a more recent British installation for monitoring the level of molten glass in the feeder to a bottle-making machine. In this model, which operates through two brick and refractory walls each 9½ in. thick, encased in ⅜-in. steel, a cobalt-60 source of activity 200 mc. is used in conjunction with a water-cooled, all-metal Geiger counter as detector. Indications of changes in glass level up to ± ¼ in. are obtained, with a sensitivity of about ± 0·01 in. Gradual radioactive decay is compensated by increasing the electronic sensitivity, so that the cobalt-60 source (much cheaper than radium) can be used over a period of five years. About one hundred such instruments are now installed, but only a few employ the desirable feature of automatic control by servo adjustment of the screw feed.

Mr. Jones outlined other possibilities for using simple level gauges to operate high-level warning systems, on batch silos and hoppers, and also mentioned the possibilities of using thickness gauges for the inspection of bottles and sheet glass.

Dr. R. E. Bastick (Chance Brothers, Ltd.) described the "Development of Glasses for Use with Radioisotopes and other Sources of Radiation", with particular reference to their uses for screening. He outlined the calculation of lead equivalent and showed that experimental determinations of this are in agreement within 1 or 2 per cent. Lead equivalents up to 0·6 were reported for some lead glasses.

Dr. Bastick then discussed the coloration of crown and flint screening glasses by large doses of radiation and showed results of doses up to 10^7 r. on flint glass and the subsequent fading observed. The use of cerium oxide as an additive to inhibit coloration was described, with data showing the inhibitory effect of various quantities of cerium dioxide in flint glass at a total dose of 10^7 r.

Neutron absorbing glasses containing oxides of cadmium and boron were described, and the dependence of absorption coefficients on neutron energy was shown.

A brief account of the use of a lead glass scintillator in a Cerenkov counter was given, and the use of cobalt loaded borosilicate glass for gamma-ray dosimetry was described.

In discussion on this paper, the special property of quartz glass in withstanding gamma-radiation up to 10^8 r. without coloration was mentioned, and the purple coloration produced by radiation when 4–6 p.p.m. of aluminium is incorporated was proposed for dosimeters which show little or no fading. It was also noted that denser glasses required smaller concentrations of cerium dioxide to inhibit coloration (for example, plate glass requires 2 per cent, while lead glass needs only ½ per cent).

Mr. J. L. Putman (Atomic Energy Research Establishment, Harwell) then presented a short paper on the "Determination of Selenium in Glass by a Radioactivation Method", an investigation made in collaboration with the British Glass Industry Research Association. He remarked that in finding the retention by glass of selenium added as a decolorizer, colorimetric methods were not applicable because of their dependence on the chemical form of the sample, and chemical analysis was cumbersome. In the method described the simultaneous neutron irradiation, in a reactor, of glass samples with and without the selenium additive was followed by comparison in a differential gamma-ray spectrometer, which subtracted the response of one sample from another, leaving only the gamma-ray spectrum due to selenium-75. Determination was thus specific for the element and largely independent of other impurities. Concentrations of 19·5 p.p.m. were measured with an estimated accuracy of ± 5 per cent. The applicability of the technique to analysis of other constituents and to the use of non-radioactive tracers was suggested.

In the afternoon, Mr. B. E. Moody (United Glass Bottle Manufacturers, Ltd.) described an "Investigation of Glass Flow in Furnaces by Radioactive Tracers". To trace the flow through furnaces handling 90 tons a day, over a period of 12–14 days, phosphorus-32 was chosen as the tracer, thus avoiding radiation hazards from the high activity of radioactive glass in the furnace, since it emits only beta particles. The tracer was in the form of neutron-irradiated ground phosphate glass compatible with the melt, and contained 51 per cent phosphorus pentoxide. After a delay of one week to allow radioactivity of potash and alumina constituents to decay, the phosphate glass contained 2 mc./gm. of phosphorus-32. It was added to the feed of one or more of three batch chargers over a period of ½ hr. From 35 to 350 mc. of phosphorus-32 was used in an investigation, 175 mc. being found to be the optimum activity.

Samples were taken at intervals from the output of three bottle-making machines fed by the furnace and measured with an end-window Geiger counter. By using a metal iris to limit the area inspected by the counter and by using glass samples thicker than 3 mm., it was established that the shape of the samples did not critically affect the results, and pieces of bottles were conveniently used for measurements.

It was found that tracer added to one of the outside batch chargers appeared almost uniformly in the three bottle-making machines, indicating good mixing and absence of streaming in the furnace. After a delay of 7½–10 hr. for amber glass and 5–6 hr. for flint, radioactivity began to appear in the product, reaching a maximum in about 24 hr. This was followed by a nearly exponential decay, leaving only 1·4 per cent of the labelled glass after 12 days and undetectable activity after 14 days. Apart from the expected initial delay before marked constituents appeared in the product, agreement with the 'curve of perfect mixing' was fairly good. Some subsidiary peaks in the curve of activity versus time were unexplained, but some were believed to be due to the recycling of active cullet.

Mr. R. F. Barker (Pilkington Brothers, Ltd.) gave an account of an "Investigation of Glass Flow in Furnaces by Radioactivation Methods". The furnace described was producing 6·4 tons per hr. of soda lime silica glass and had a capacity of 1,350 tons. Measurements were required over a period of several weeks. The long half-life and high activity required in a radioactive tracer made the use of radioactivity in the furnace undesirable. Hence an inactive material which could be made radioactive by the subsequent neutron irradiation of samples was used. Tantalum was chosen because of its high neutron cross-section and the desirability of the gamma-emitting tantalum-182 formed on neutron irradiation, the half-life (110 days) of which was longer than that of any activity induced in the normal constituents of the glass. The tracer was in the form of 3¾ kgm. of tantalum peroxide.

Tests were made on three of five machines fed by the furnace, and 200 samples, each containing 5 gm. of powdered glass, were irradiated in a reactor at Harwell. After a delay of five weeks to allow short-lived activities to decay, measurements were made with a scintillation counter, using a single-channel pulse amplitude analyser to distinguish the tantalum-182 gamma rays. A minimum transit-time of 4 hr. was found, in agreement with other data. The tracer was at a maximum after 100 hr. and its decline was followed over a total time of 520 furnace-hours. Moderate agreement was found with W. M. Hampton's theoretical curve for perfect mixing, but Mr. Barker directed attention to significant departures from this curve near the time of injection.

In a second paper, on "The Assessment by Tracer Methods of Mixing during Sand Treatment", Mr. R. F. Barker described experiments made in collaboration with the Isotope Division, Harwell, using sand labelled by immersion in a solution of barium-140 and subsequent heating at 500° C. The adhesion of the radioactive material was already established under conditions of abrasion and washing with water. The daughter isotope lanthanum-140 (40 hr.) reaches equilibrium with the barium-140 (12 days) and measurements were made of gamma rays from the lanthanum.

Ten pounds of labelled sand, carrying 100 mc. of barium-140, were mixed with 5 cwt. of inactive sand in a cement mixer and added to a hopper feeding the washing plant. The progress of the radioactive material through the washing plant and grader was registered by recording meters placed outside the steel pipes carrying the sand slurry. A survey was made of the horizontal distribution of radioactively labelled sand in the storage bin (capacity 2,000 tons). At this stage the labelled sand was found still to be fairly localized. Further monitoring of the sand leaving the bin and in the railway transit wagons showed that mixing was introduced by the method of loading.

Finally, timed measurements were made of the radioactivity of glass drawn off from the tank furnace. From an analysis of these results the distribution of a particular sample of the original sand in the finished product was assessed.

The papers were followed by lively discussion. The proceedings of the symposium will be published in the *Journal of the Society of Glass Technology*.

J. L. Putman

MELTING AND DIFFUSION

The second symposium on "Melting, Diffusion and Related Topics" was held at the National Research Council Laboratories, Ottawa, on October 21–22. The meeting was sponsored by the Low Temperature and Solid State Physics Group of the Division of Pure Physics, National Research Council of Canada. As in the previous symposium, reported in *Nature* (177, 23; 1956), the object was to bring together workers with varied approaches to the subject and, by limiting the number of formal contributions to twelve, to encourage informal discussion.

In the previous symposium the melting process itself was a major topic of interest. In contrast, the programme on this occasion was concerned chiefly with processes having only a general bearing on melting, the direct approach being temporarily abandoned in favour of seeking clues from the solution of associated problems.

Among the papers concerned with measurements in the region of melting was one by D. L. Martin (National Research Council), who reviewed existing information concerning specific heat anomalies in the region of melting; he showed that both anharmonicity and lattice defects have been invoked in explanation but argued that little conclusive evidence exists as to their relative importance. N. H. Nachtrieb (Institute of Metals, Chicago) dealt with diffusion in liquid and solid pure metals and in alloys; the analysis of his measurements showed a clear relation between melting and diffusion parameters, but also underlined the restricted nature of purely thermodynamic arguments. Diffusion was also considered by J. A. Morrison and R. Rudham (National Research Council), who gave details of their identification of the mechanism of the anion diffusion process in sodium and potassium chloride crystals. Slow neutron diffraction measurements were described by a group of workers from Chalk River: D. G. Henshaw and N. K. Pope gave complementary experimental and theoretical accounts of the determination of the radial distribution function in solid and liquid helium and neon and in liquid argon, while B. N. Brockhouse showed how the incoherent scattering could give information on molecular motions and may provide a means of resolving some of the indeterminancies involved in the direct measurement of diffusion.

A second group of contributions dealt with transitions other than melting. R. W. Smith (University of Toronto) described investigations on the grey tin/white tin transformation carried out in Birmingham with G. V. Raynor, in which previous uncertainties of observation have been positively correlated with impurity content. D. Gugan and J. S. Dugdale (National Research Council) gave a preliminary report of work in which electrical resistivity measurements appear to provide information on the martensitic transformation in lithium. Z. S. Basinski (National Research Council) outlined a theory of work hardening of face-centred cubic metals in which the main obstacles were provided by the 'forest' of dislocations; the theory appeared to apply also to body-centred cubic metals, but in that case at low temperatures the mechanical properties were dominated by a large Peierls–Nabarro force. Work on the liquid state was represented by an account given by A. C. Hollis Hallett (University of Toronto) of recent experiments on the viscosity of liquid helium.

The single contribution dealing specifically with melting was by J. S. Dugdale, who discussed the Lindemann melting formula in relation to inert gas solids. R. J. Uffen (University of Western Ontario) once again made a convincing defence of large-scale approximation and extrapolation, this time discussing certain tectonic and volcanic phenomena in terms of the pressure dependence of melting of various types of magma.

In these days of high-speed conferences it is pleasurable to report on one at which the pace and length of discussion were such as to enable at least one non-expert to participate with profit. An informal report of the proceedings is in preparation.

J. W. LEECH

ELECTRONICALLY EXCITED SPECIES

A SYMPOSIUM on "The Structure and Reactivity of Electronically Excited Species" was held at Ottawa during September 5–6 under the auspices of the Physical Chemistry Division of the Chemical Institute of Canada.

In his introduction to the section on structure, G. Herzberg directed attention to the rapid increase, recently, in the number of polyatomic molecules, radicals and ions for which rotational and vibrational analyses of electronic systems had been carried out. This had demonstrated that, in many cases, the shapes in the excited states are different from those of the ground-states. For example, acetylene, hydrogen cyanide and carbon disulphide are linear in their ground-states but bent in their first electronically excited states. Throughout the meeting it was clear that the predictions made by A. D. Walsh in 1953 had been substantiated most impressively. References were repeatedly made to Walsh's energy diagrams.

G. W. Robinson and V. E. DiGiorgio showed in a submitted paper that formaldehyde is non-planar in a low-lying excited state, while K. Allison and A. D. Walsh concluded that the same may be true for one or two of the excited states involved in the Rydberg transitions. G. W. King presented evidence for the conclusion that there is only a small change in molecular geometry on exciting the glyoxal molecule in the transition studied by him.

During this part of the meeting much interest was shown in the interactions between electronic and vibrational motions of polyatomic molecules. M. H. L. Pryce, U. Opik, H. C. Longuet-Higgins and R. A. Sack dealt theoretically with the dynamical Jahn-Teller effect, considering the energy-levels of a non-linear molecule in a doubly degenerate electronic state which is split by a doubly degenerate vibrational mode. K. Dressler and D. A. Ramsay dealt with the Renner effect in linear molecules. The lowest state of linear NH_2 would be a Π state. Experimental results suggest that the ground-state is bent and the first excited state is linear, the vibrational levels of the hypothetical linear state correlating with the levels of those two states, half with those of the excited and half with those of the ground-state. The ground- and excited states are degenerate when the radical is linear but different in energy when it is bent. The radical HCO appears to behave similarly.

Two papers by J. N. Murrell and by D. S. McClure were submitted which discussed the transfer of electronic and vibrational energy between weakly coupled systems. This is a subject of very great interest at the moment.

In addition to molecules and radicals the excited states of ions were discussed during the meeting. D. C. Frost and C. A. McDowell described their mass spectrometer which has been employed to determine the energies of the excited states of the ions produced in the instrument. This complements information that can be obtained spectroscopically, though so far detailed analyses of polyatomic ionic spectra are only available for CO_2^+, CS_2^+ and $C_4H_2^+$. Also J. W. Sidman, in an interesting paper, described results obtained for the nitrite ion in the crystalline state. From these he obtained information concerning the vibrational and lattice frequencies of the ground- and excited states.

There is doubt about the multiplicities of the excited states of some molecules and, in this connexion, A. E. Douglas presented some results for the Zeeman effect in the near ultra-violet bands of carbon disulphide. This indicates that the excited state is a triplet. G. W. Robinson and V. E. DiGiorgio concluded that the weak bands of formaldehyde studies by them were due to a singlet–triplet system.

On the theoretical side R. S. Mulliken suggested that it may soon be possible to make more reliable calculations of the energies of excited molecular states. He presented results for carbon monoxide, nitrogen and acetylene and for several molecules of the AB_2 type. The possibility of chlorine dioxide in the excited state being unsymmetrical was discussed, since the antisymmetric vibration appears to be excited on going to the upper state. J. W. Linnett discussed the electron distribution in the ground- and low-lying excited state of acetylene by transforming the molecular to equivalent orbitals. On this basis it was possible to understand why the carbon–carbon bond-length in the excited state is about the same as that in the ground-state of benzene and why the molecule is bent.

E. W. R. Steacie gave the introductory paper to the section on reactivity and pointed out that, while the evidence for excited species occurring in chemical processes had in the past often been very meagre, firmer knowledge of their participation in reactions is now being obtained. H. Eyring also gave a broad survey of the field and stressed the value of potential energy surfaces when considering chemical reactions theoretically.

There were several interesting theoretical contributions to this section. R. A. Marcus considered the case of electronically excited molecules reacting unimolecularly, the course of reaction being examined as motion on a potential energy surface. B. Stevens pointed out that while totally symmetric vibrations are excited when an electronic transition occurs, the excitation of non-totally symmetric vibrations are usually necessary for dissociation. A transfer of energy must therefore occur, and this will depend on the anharmonicity. Stevens suggested that the dissociation rate will consequently depend on the magnitude of optical energy taken up. E. K. Gill and K. J. Laidler discussed theoretically the reaction:

$$\mathrm{Hg}^*(^3P_1) + \mathrm{O}_2(^3\Sigma_g^-) \rightarrow \mathrm{Hg}(^1S_0) + \mathrm{O}_2^*$$

They reached the conclusion that both the theoretical and experimental evidence leads to the view that oxygen is produced in the $^3\Sigma_u^+$ state. This involves the minimum transfer of energy from one form to another. Potential energy surfaces were used by these authors also.

H. E. Gunning described experiments which made use of a mercury-vapour lamp charged with mercury-202. With this, mercury-202 could be excited in ordinary mercury vapour in the presence of gases with which the excited mercury could react. Isotopic enrichment in a solid product indicated that this was formed in a primary process; no enrichment indicated that it was formed secondarily. No enrichment in mercuric oxide was obtained from nitrous oxide and oxygen but enrichment in mercurous chloride was found with hydrogen and methyl chlorides and with carbon tetrachloride.

J. D. McKinley and S. C. Polanyi had mixed atomic sodium with atomic and molecular hydrogen. They discussed the reactions that might lead to the chemiluminescence (sodium D lines) that is observed. J. C. Polanyi and also C. L. Arnot and C. A. McDowell discussed the results they had obtained for the rate of transfer of vibrational energy to translational when iodine is excited by the mercury green line to the twenty-sixth vibrational level of the excited state in the presence of inert gases. The competition between energy transfer and fluorescence is studied. Arnot and McDowell found that the ratio of rates was greater than expected from theory and suggested that the fluorescence lifetime may be less than has been supposed.

T. M. Sugden and E. M. Bulewicz and also F. Kaufman described work on the green emission that is obtained when nitric oxide is added to systems containing oxygen atoms. The former workers concluded that the intensity of the glow is determined by a more complicated process than the simple combination of atomic oxygen and nitric oxide.

G. J. Minkoff discussed the polymerization of acetylene and considered the possibility that a bent triplet diradical might be involved in the mechanism.

H. P. Broida and K. E. Shuler described the use of the reversal of iron lines in studying flame temperatures. This proves to be a sound method if equilibrium is established. Moreover, it is possible to discover when equilibrium is not established. P. Carrington had studied the emission by $^2\Sigma^+$OH radicals in oxy-acetylene flames. It appears that the electronically excited radicals are deactivated at nearly every collision, so any departure from the equilibrium distribution that is observed must represent the situation prevailing on the production of the excited radicals.

J. Heicklen and W. A. Noyes described photochemical experiments that had been carried out with ketones and bi-acetyl. In the latter case they concluded that triplet excited molecules were involved. They discussed the decomposition, fluorescence and phosphorescence of these substances. H. Okabe described work on the fluorescence and photolysis of hexafluoroacetone. The effect of pressure and the addition of foreign gases was studied.

PHYSICS Dept.

SUPPLY AND DEMAND

PROF. M. G. Say delivered his chairman's address before the Supply Section of the Institution of Electrical Engineers on October 23. The address, which was given under the title "Too Much and Too Little", was by no means confined to strictly technological considerations, and constituted, rather, a broad philosophical review of the persistent disparity between demand and supply, between needs and resources. Commenting on the use of the figure representing the power available per head of the population as an index of the standard of civilized life, Prof. Say remarked that in North America, Western Europe, and the Soviet Union, energy resources were being developed as fast as practicable, while in the underdeveloped countries—representing three-quarters of the habitable world and two-thirds of the world's population—the demand for auxiliary energy was beginning. With the development of nuclear energy the production of electric power, which until now had been dependent upon coal, oil, or water-power, had become largely independent of geography or geology. It must, however, be remembered that a country might remain poor and underdeveloped because poverty put out of reach the opportunity to build up the supply of power which would enable development to take place.

The total world consumption of power in the year 1950 was some 30,000 million kilowatt-hours. On a United Nations estimate of the annual rate of increase of power consumption at 3¼ per cent the year A.D. 2000 would see a three-fold increase on the present demand for power. This must be met very largely from nuclear energy, for by that time coal and oil outputs would be well past their peaks and hydro-electric power would be approaching its full development. It should be noted that the present methods of generating electric power, by means of a thermal cycle, were inherently wasteful, nearly four-fifths of the available heat being rejected. If this rate of loss should continue the world would in fifty years' time be wasting heat in the production of electricity at a level in excess of twice the present total world consumption of power.

Referring to engineering as a career and to the present shortage of engineering graduates, Prof. Say drew a comparison between the situation in the U.S.S.R. and in Britain. It was worth noting that despite the scale of the Russian need for engineers and scientists there was no extreme specialization in science in the secondary schools. In the U.S.S.R. the three final years of school, to age seventeen, included the study of physics, chemistry and mathematics for about 40 per cent of the time, and this held for all pupils, arts as well as science. Thus potential arts men had to pass examinations in science subjects while potential engineers and scientists had to study literary subjects to a level quite beyond that of the average British technical student.

The concluding section of Prof. Say's address was concerned with the ultimate values in human life and the possible threat which was offered by the pressure and strain of a mechanistic age to the qualities of imagination and creation which were key elements in the human make-up. "We cannot deny," he said, "that the threat exists, nor on the other hand that industrialization has brought great benefits to mankind. It will bring more, but only if the mastery remains where it belongs—in the care of the human spirit." J. GREIG

NATURAL HISTORY OF THE FOX SQUIRREL

A FIELD study of the fox squirrel (*Sciurus niger*) in the south-eastern coastal area of the United States has been made by J. C. Moore (*Bull. Amer. Mus. Nat. Hist.*, 13, Art. 1). The fox squirrel has probably diminished greatly in numbers and range because of changes wrought by man. *Sciurus niger shermani* was investigated in the sand hills of north Florida in a fir-maintained plant community which is common over a wide area of the south-eastern coastal plain, the *Pinus australis–Quercus laevis* associates. This plant community was changed suddenly and radically from a tall but very open forest of primeval long-leaf pines with turkey oak indifferently represented as a secondary, lower level dominant, to a virtually pure stand of turkey oak, relatively close-ranked and low.

Moore's inquiry was designed to determine how this large tree squirrel, after presumably evolving in the open stands of large pines, lives now in the lowly oak forest which has succeeded the logged-off pine.

The principal predatory enemies of *Sciurus niger shermani* are apparently the bald eagle, the red-tailed hawk, and man. There are few suitable refuges for so large a tree squirrel in this low, open forest of deciduous trees and this may have brought about the following developments in behaviour unusual for a tree squirrel: a fairly well-established tendency for it to take refuge, when hard pressed, in the burrows of gopher tortoises underground; the use by the fox squirrels of hollows that extend down through the tops of old stumps to nesting chambers underground; an escape behaviour, which may have developed since the removal of the old pines and which is presumed to be employed only against man, that involves hiding in the top of a second-growth long-leaf pine by ascending the plume-like apical twig so that the twig bends over horizontally under the squirrel, and the squirrel lies on top hidden from all below; there is, apparently, an excessive number of leaf-nests per individual squirrel, thus providing more refuge.

While these forms of behaviour have survival value, they do not enable the animal to prosper.

THE BRITISH COUNCIL

THE annual report of the British Council for 1956–57 refers briefly to the review of Overseas Information Services made by Dr. C. Hill. The decisions recorded in the White Paper accepted about nine-tenths of the Council's proposals for increased activities and the Council specially welcome the reference to co-operation with people and interests outside the Government. The Council's work depends largely on the help and advice of many educational, professional, scientific and industrial bodies as well as of thousands of individuals. About half the report deals with the Council and the sciences and an increasing proportion of the Council's work consists of making known British scientific achievement, assisting the dissemination of information to the appropriate specialists and in serving as a link between British experts and professional bodies and their opposite numbers abroad. Allied to this is assistance in training. Since 1950, the number of overseas students in the United Kingdom has risen from 10,000 to nearly 35,000, about a third of whom are at universities or university colleges, while 60 per cent are concerned with the sciences. By far the largest increase in students is among those attending technical colleges, and the numbers might be greater still if their countries could find the necessary funds or Britain could offer scholarships and places on the scale of some of her competitors.

The report stresses Britain's advantage, shared with the Commonwealth and the United States, in the establishment of the English language among scientists as an essential means of communication, and the Council's work in furthering the study of English is thus of importance in this connexion. The

University of Edinburgh inaugurated its new School of Applied Linguistics in October 1957. This is conceived especially for those who are responsible for training teachers of English and the establishment or revision of teacher-training methods. Three Council officers are participating in the course together with experts in teaching English from overseas invited by the Council. English language teaching now occupies so important a place in the Council's activities that the English Studies Advisory Committee has been divided into two separate panels, one advising on literature and the other on language.

In fostering the knowledge of British scientific achievements, the Council's special function is to use its staff in the field to find out what demands for information and training are being left unsatisfied and to put learned institutions and individual scientists overseas in touch with the appropriate organization or individuals here. Even within the Commonwealth the established links are not always adequate and the Council has been able to reinforce them by, for example, the exchange of delegates between the British Association and the corresponding organizations in Ceylon, India and Pakistan, by showing medical films in the more advanced Colonies, sending lecturers on such subjects as the use and local manufacture of laboratory apparatus, or enlisting the help of specialists who happen to be visiting the territories.

The Council's most important role in the sciences is in promoting visits by scientists to and from Britain for discussion, observation and study, and of all the visitors to Britain for which the Council makes arrangements about 13 per cent are financed by the Council. In the past five years the Council has assisted in some 7,000 visits of individuals in the sciences, or about 32 per cent of the total for all subjects. Of the Council's postgraduate scholarships, 594 or 56 per cent of the total in the past five years went to the sciences, and for the 221 awards in 1956–57 there were 2,500 applicants. The Council is also the national supervising agency for the United Nations Technical Assistance Administration Fellowship Scheme and other Fellowship Schemes of the Specialized Agencies under which 2,941 Fellows have visited the United Kingdom during the past ten years, of whom about two-thirds were concerned with science and technology, medicine, agriculture and training leading to development. Among the short-term visitors, the proportion whose interests lie in science has increased since 1950 from 25 to 30 per cent, but among the bursars it has increased from 25 to 40 per cent. There have been few changes in emphasis as regards subject, though interest in the nuclear sciences has grown and the organization of technical education has greatly increased, while the steadily growing demand for British professors, lecturers and teachers is reflected in the number of rectors of overseas universities, senior officials of Ministries of Education, and principals of teacher-training colleges who have sought the Council's help, first to study the organization of research in Britain and our methods of teaching scientific and technical staff, and then in recruiting British staff for their own institutions.

The Council operates two schemes for the interchange of university teachers, one dealing with Western European countries and the other with the Commonwealth, under which 161 scientists from United Kingdom universities have visited thirteen European countries and 62 have visited Commonwealth countries. There have been 154 reciprocal visits from foreign countries and 200 from the Commonwealth, the percentage of all these visits devoted to the sciences being 60. Under the interchange scheme for younger research workers started in 1954 there have been 33 visits from the United Kingdom to four European countries and 27 visits from these countries to the United Kingdom. Stress is also laid on the lecture and advisory tours of specialists which the Council organizes in co-operation with overseas countries, and in 1956–57 the Council initiated a pilot project to enable British experts to visit and work in Latin American universities and research institutions under which four such visits were arranged between July 1956 and March 1957. During the past five years the Council has accepted responsibility for recruitment to some forty vacancies for British scientists in teaching posts in universities and schools, but not all these have been filled.

More than 6,000 British papers from learned periodicals were supplied in 1956–57 and more than 400 specialists from some 70 countries visited the Council's medical and science libraries. Noteworthy among the group exchange visits with the U.S.S.R., arranged by the Soviet Relations Committee of the Council, were the exchanges of delegations between the Royal Society and the U.S.S.R. Academy of Sciences; between the Royal College of Surgeons of England and the Royal College of Surgeons, Edinburgh, and Russian surgeons; and exchanges of delegations interested in engineering education and training, whose programme in Britain was organized by the major engineering institutions. These visits, as Sir David Kelly emphasizes, were in marked contrast to others, non-reciprocal, since the Soviet delegations were interested simply in acquiring technical information.

DIAMONDS IN SIBERIA

By Prof. S. I. TOMKEIEFF

University College of Science
PHYSICS Dept.
92, Upper Circular Rd, Calcutta

UNTIL quite recently no diamond deposits in the territory of the U.S.S.R. were known, while at the same time the rapid progress of industrialization was pressing for a supply of industrial diamonds, which had to be imported from abroad. This prompted the Soviet Government, through the appropriate channels of the Geological Survey, the Ministry of Geology and the Academy of Sciences, to embark on a series of planned explorations for diamonds. In 1941, diamond placers were discovered in the Urals, but these proved to be of no commercial value. In 1944 the wild tracts of taiga, situated between the rivers of Enisey and Lena, were selected as a possible diamantiferous region, and this selection proved to be a correct one, for in 1948 diamond placers were discovered in the basin of Nizhneya Tunguska, in 1949 in the basin of Vilui, and finally in 1954 the first kimberlite pipe, named 'Zarnitza', was discovered in the basin of Daldyn, in the north-west Yakutia. Subsequent explorations and prospecting greatly extended the diamantiferous area situated between the Enisey and Lena.

This work, which began during the War, was carried out in an atmosphere of secrecy, and no results were published in scientific periodicals. Only recently, when rumours about Siberian diamonds began to be more persistent, has a popular account of the results of this exploration been published (V. S. Trofimov, *Priroda*, No. 7, 10; 1957). This article, published in a Russian popular science journal, gives a clear and comprehensive account of the diamond fields of Siberia, and is provided with a map showing the distribution of the deposits and illustrated by numerous photographs including two colour photographs of kimberlites.

The diamantiferous province is situated in the Central Siberian Plateau. Its approximate boundaries form a rectangle, 400 km. by 1,500 km. in size, stretching in a north-easterly direction from the River Angara in the south, to the River Lena between Muna and Vilui in the north-east. The whole of this area is situated in the region of taiga (north coniferous forest zone), which has a permanently frozen ground, severe climate and a very sparse population. The exploring and prospecting were mainly along the water courses at first. Operations included sampling alluvial deposits, mapping out placers and tracing pay streaks to their sources—the kimberlitic pipes. In this way several dozen kimberlite pipes were discovered in the north-western Yakutia, the only region where commercial diamonds were found both in the pipes and in the placers. The pipes pierce limestones, dolomites and marls of Cambrian and Ordovician times, but fragments enclosed in them suggest that they are of Jurassic or Cretaceous origin. All the pipes are found in a belt 1,000 km. long, 250 km. wide at the northern end and 35 km. wide at the southern end. Kimberlite is a brecciated rock containing fragments of various rocks, and crystals of pyrope, olivine, chrome-diopside, ilmenite and other minerals, including the rare diamond, but Siberian kimberlite contains little phlogopite. The pipes are oval or irregular in cross-section, with a diameter varying from 50 m. to 550 m. The usual zoning from 'yellow ground' to 'blue ground' and finally to 'hard-bank' kimberlite is rather poorly developed, probably because of the severe action of the frost, which disintegrated the solid rock of the ground water level. In some pipes several intrusive phases of kimberlite are present; for example, in the pipe 'Zarnitza' there are five columns of kimberlite, each successive phase enclosing fragments of the previous phase. The yield of diamonds from kimberlite pipes is sometimes higher than 1 metric carat per cubic metre.

Towards the end of 1956 the following groups of Yakutian pipes were located: Malo-Batuobinskaya (middle course of Irelyakh, left tributary of Malo-Batuobi, tributary of Vilui), Daldynskaya (basin of Daldyn, left tributary of Markh), Alakitskaya (upper reaches of Alakita, right tributary of Olenek), Munskaya (upper reaches of Muna, left tributary of Lena), Olenekskaya (middle and lower reaches of Olenek).

The diamantiferous alluvial deposits adjoining the kimberlite pipes in the north-eastern part of the province contain pay placers, but those of the south-western part of the province, presumed to be originally of a Pre-Cambrian age, are of no commercial value. The yield of diamonds in placers varies from 0·01 carat to several carats per cubic metre. The richer placers are situated in the basin of the Vilui River.

Siberian diamonds are rather heterogeneous both in their size and in their quality. Every region is characterized by certain types of diamonds. In size they vary from a fraction of a carat to 32·5 carats, but stones above 0·5 carat are rare. The bulk of stones extracted are less than 0·1 carat in size. The average for all stones hitherto extracted is 0·07 carat. The majority are colourless. Coloured stones (yellowish-brown, smoky, and rare greenish and pinkish) are found in the south-western part of the province. Inclusions of graphite, olivine, pyrope and small diamond crystals are often found in Siberian diamonds. Their quality is not very high. Stones of gem quality form 9–38 per cent of the total, the remainder being industrial diamonds.

No figures, as yet, are given relating to annual production, methods of working, or industrial applications of Siberian diamonds.

Additional information relating to the kimberlite pipes is provided by L. N. Leontiev and A. A. Kadensky (*Doklady Akad. Nauk S.S.S.R.*, **115**, 368; 1957). The age of pipes is definitely fixed as Triassic, more or less contemporaneous with the wide-spread intrusions and extrusions of basalt and dolerite belonging to the series of the so-called 'Siberian Traps'. The great depth, of a few kilometres, of the foci of explosions of the pipes suggests that the kimberlite is not derived from the periodotite mantle of the Earth, but is genetically connected to the alkaline variety of basic magma. The grouping of pipes suggests that they are placed along certain important tectonic features of the Earth's crust, such as flexures and tectonic breaks.

ADENOSINE TRIPHOSPHATE METABOLISM IN THE RABBIT ERYTHROCYTE *IN VIVO*

By DR. BERTRAM A. LOWY, DR. BRACHA RAMOT and DR. IRVING M. LONDON

Departments of Medicine and Biochemistry, Albert Einstein College of Medicine–Bronx Municipal Hospital Center, New York

ADENOSINE triphosphate is known to play a key part in the metabolism of many cells, including the erythrocytes of numerous species. It serves as a source of energy and as an essential component of many biosynthetic reactions and participates in co-enzyme synthesis. Although the active turnover of the labile phosphate groups of adenosine triphosphate has been investigated[1], little is actually known concerning the turnover of the remainder of this molecule. Knowledge of the biochemical origin and metabolic behaviour of adenosine triphosphate within the erythrocyte may provide some insight into the mechanisms which determine the life-span of this cell.

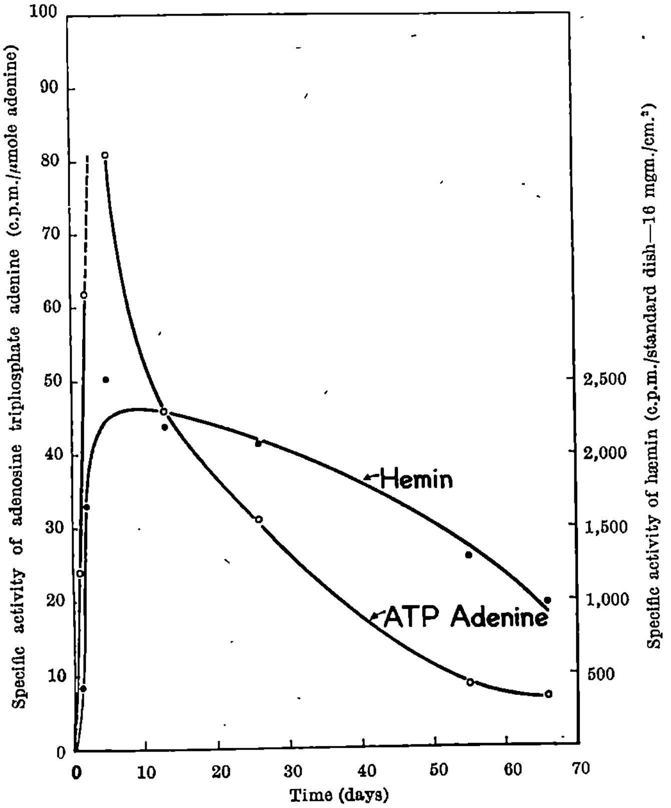

Fig. 1. Incorporation of glycine-2-^{14}C into the adenine moiety of rabbit erythrocyte adenosine triphosphate and into the hæmin of hæmoglobin

The synthesis of the adenine portion of rabbit erythrocyte adenosine triphosphate *in vivo* has been studied in order to determine the extent to which the purine moiety arises from glycine-2-^{14}C, a known precursor of purines. The metabolic behaviour of this adenine moiety has been investigated in terms of whether it resembles hæmoglobin in its metabolic stability[2,3], or is more closely related to cholesterol[4] or glutathione[5], which have been found to undergo turnover during the life of the human erythrocyte.

A number of white male New Zealand rabbits received single subcutaneous injections of 1·0 ml. of glycine-2-^{14}C in 0·9 per cent sodium chloride solution containing 0·2 millimole per ml. with a specific activity of 1·0 millicurie per millimole. After periods of time ranging from 24 hr. to 66 days, one or two rabbits were heparinized and bled by heart puncture shortly after intraperitoneal administration of 2·5 ml. of 25 per cent magnesium sulphate solution. Hind-leg muscles were removed for adenosine triphosphate preparation, and nucleic acids were isolated from the internal organs. These aspects of this work will be reported in detail elsewhere.

Erythrocytes were washed three times in cold 0·9 per cent sodium chloride solution after removal of the plasma and buffy coat. The final sample of erythrocytes had less than 0·01 per cent contamination with white cells.

Adenosine triphosphate was extracted with cold trichloracetic acid, and the barium salt was prepared[6]. The barium precipitate also contained adenosine diphosphate, adenosine monophosphate, sugar phosphates, phosphoglyceric acids and inorganic phosphate. Partial purification of the adenosine triphosphate was effected by ion exchange chromatography on 'Dowex-1-Cl' resin[7]. A mixture of adenosine triphosphate and 2,3-diphosphoglycerate, free of the other constituents of the barium precipitate, was eluted by 0·06 *N* hydrochloric acid. The adenosine triphosphate was hydrolysed with *N* hydrochloric acid by heating for 1 hr. in a boiling water bath without affecting the 2,3-diphosphoglycerate, which is markedly resistant to acid hydrolysis. The resultant mixture of adenine, ribose-5-phosphate and 2,3-diphosphoglycerate was adjusted to *p*H 9·0–9·5 with *N* ammonium hydroxide and passed through a 'Dowex-1-Cl' column. Adenine was eluted with 0·001 *N* hydrochloric acid, and purity was established by spectrophotometry, paper chromatography, and ribose and phosphorus analyses.

Aliquots of the eluates were plated on planchets at infinite thinness and assayed for radioactivity in a 'Nuclear-Chicago' gas flow counter with a micromil window. Rechromatography and elution from 'Dowex-1-Cl' resin and from Whatman No. 1 filter paper resulted in no change in specific activity.

Hæmin was prepared from a small aliquot of washed erythrocytes. Standard samples, recrystallized to constant radioactivity, were assayed.

The results, summarized in Fig. 1, indicate that glycine-2-^{14}C serves as a precursor of the adenine moiety of erythrocyte adenosine triphosphate. They also confirm[3] the stability of the hæmoglobin of the rabbit erythrocyte during the 65–70 day life-span despite the somewhat greater lability of the rabbit erythrocyte compared to that of the human red cell[2]. In contrast to the relative metabolic stability of the hæm, the metabolic behaviour of the adenine portion of the adenosine triphosphate is clearly different since the specific activity of the adenine declined exponentially after about the fifth day and reached a very low activity after about 55 days.

In order to explain the decline in the specific activity of the adenine, several possibilities, which may not be mutually exclusive, should be considered. One possible explanation is that the mature erythrocyte is capable of synthesizing the purine portion of adenosine triphosphate. This would result in a gradual decrease in its specific activity. Thus far, however, in several experiments in this laboratory *de novo* synthesis of adenosine triphosphate adenine from glycine-2-^{14}C has not been demonstrated in the mature erythrocytes of rabbit or man, *in vitro*. Although these preliminary experiments do not eliminate the possibility of a biosynthetic mechanism, they suggest that a complete pathway may be lacking. The possibility of the absence of a purine-synthesizing system in the mature mammalian erythrocyte is compatible with the absence of a number of other common metabolic processes, such as the synthesis of nucleic acid and protein, the Krebs tricarboxylic acid cycle, and the cytochrome system. It is also of interest to note[3] that in rabbit bone marrow, *in vitro*, there is a limited ability for the synthesis of nucleic acid purines from formate-^{14}C. Further studies bearing upon this problem are in progress.

Dilution of the isotope as a result of an exchange with preformed adenosine triphosphate is unlikely since there is little or no adenosine triphosphate in rabbit plasma and since the mature erythrocyte is considered to be impermeable to phosphorylated compounds. Phosphorylation of adenosine or inosine is unlikely because there appears to be no significant concentration of purine nucleosides in the peripheral blood. Furthermore, adenosine would be expected to undergo deamination by the active adenosine deaminase of the rabbit erythrocyte. Inosine is known to undergo extensive phosphorylytic cleavage in the rabbit erythrocyte.

The alternative explanation for the observations would result from a decreasing level of adenosine triphosphate in the erythrocyte during the *in vivo* ageing process so that the amount initially provided to the cell is gradually depleted. The decline in specific activity would be due to dilution by the adenosine triphosphate of younger cells in which the concentration would be at a higher level. There is some evidence bearing upon this possibility. It is known that the adenosine triphosphate concentration in reticulocytes is about 2·5 times that of mature erythrocytes[9]. The level of adenosine triphosphate in a sample of mature erythrocytes is actually an average concentration of adenosine triphosphate in a cell population of all ages. Our results may be explicable in terms of a progressive diminution in adenosine triphosphate content in each erythrocyte concomitant with ageing of the cell. If such a decline in the content of adenosine triphosphate of the aged erythrocyte occurs, it may result in the impairment of one or more reactions essential for the integrity of the erythrocyte and thus contribute to the demise of the cell. It is known that a decline of adenosine triphosphate in an erythrocyte accompanies *in vitro* ageing and, in fact, is responsible for the lost ability of *in vitro* aged cells to metabolize glucose because of the requirement of adenosine triphosphate for its phosphorylation.

The possibility that the content of adenosine triphosphate of the circulating erythrocyte is a determinant of its life-span is being studied.

This work has been sponsored by research grants from the United States Atomic Energy Commission, the Damon Runyon Memorial Fund for Cancer Research, Inc., the National Heart Institute of the National Institutes of Health, United States Public Health Service and the Office of Naval Research.

EXAMINATION OF CELLULOSE FIBRE BY THE LOW-TEMPERATURE SPECIMEN METHOD OF ELECTRON DIFFRACTION AND ELECTRON MICROSCOPY

By GORO HONJO
Tokyo Institute of Technology, Oh-okayama, Meguro-ku, Tokyo
AND
MASARU WATANABE
Japan Electron Optics Laboratory Co., Ltd., Kamirenjaku, Mitaka, Tokyo

THE electron diffraction method has the advantage of yielding fairly intense diffraction patterns from a very small amount of material. Recent techniques of electron diffraction have improved this advantage further, making it possible to confine the effective specimen area to a very small size of the order of 1 × 1 μ^2. By means of a method originated by Hillier[1] we can focus the electron beam on an area of this size in specimens. By means of the three-stage electron microscope originated by Boersch[2] and le Poole[3], we can select the specimen area from the field of the highly magnified electron image. Preston and Ripley[4] applied this method to the study of the cell wall of *Valonia*. They verified the correspondence between the textural and atomic structures of the microfibril, and observed in detail the structure of the wall, which consisted of sheets of differently oriented microfibrils.

Unfortunately, however, the atomic structures of an organic substance like cellulose fibre are so liable to be damaged by irradiation in electron beams that the crystalline diffraction patterns can be observed for only a very short time. Preston and Ripley succeeded in taking photographs of the diffraction patterns from *Valonia* microfibril by reducing greatly the irradiating intensity. They stated in their report that it was also necessary to lower the accelerating voltage of electrons to as low as 25 kV. This condition seems to us rather unfavourable. The damage to atomic structure in the specimens is considered to be caused mainly by the rise in temperature of the specimens due to the electron bombardment; and the lowering of the accelerating voltage must increase the interaction of electrons with the specimens and so increase the rise in temperature. In fact, we observed that the crystalline diffraction patterns of *Valonia* microfibril were maintained for a longer time under irradiation by 100 kV. electrons than by 50 kV. electrons, though even with the higher accelerating voltage it was not easy to maintain the patterns longer than a few seconds under irradiations of usual intensity.

In order to avoid this difficulty we devised a method of cooling the specimens. Concerning cooling devices for specimens in an electron diffraction camera and in an electron microscope, one of us

(G. H.) and other collaborators[5] have previously reported in detail.

Cooling the specimens was, in fact, very effective in protecting them from damage. It was not difficult to observe the crystalline diffraction patterns from *Valonia* microfibril for as long a time as necessary even with fairly intense irradiation, namely, with irradiations giving apparent electron micrographs of direct magnification of 5,000.

Figs. 1 and 2 reproduce two pairs of electron micrographs and diffraction patterns of *Valonia* microfibril taken by Boersch–le Poole's method. Fig. 1 was taken without cooling and Fig. 2 by cooling the specimen to −40° C. The improvement in the diffraction pattern by cooling is evident. This specimen is composed of two sheets of microfibril having fibre axes along the directions indicated by the arrows.

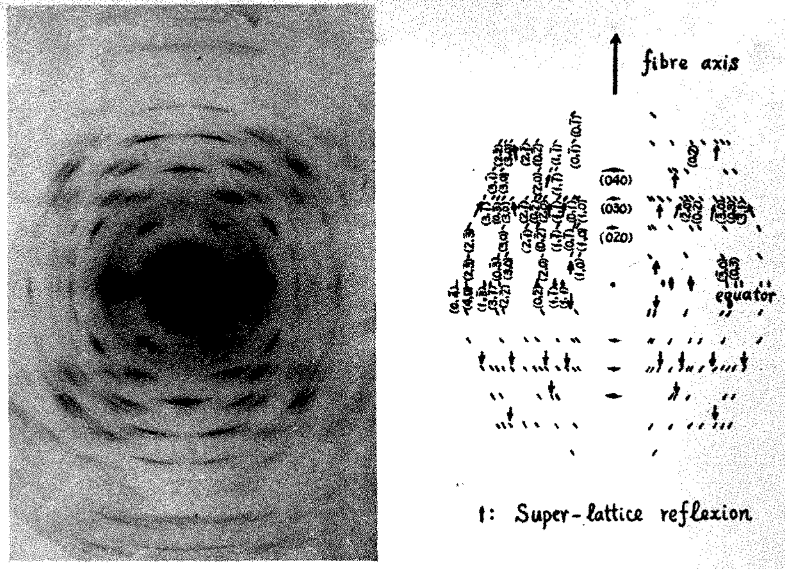

Fig. 3. Electron diffraction pattern of *Valonia* microfibril cooled to −100° C. taken by Hillier's method

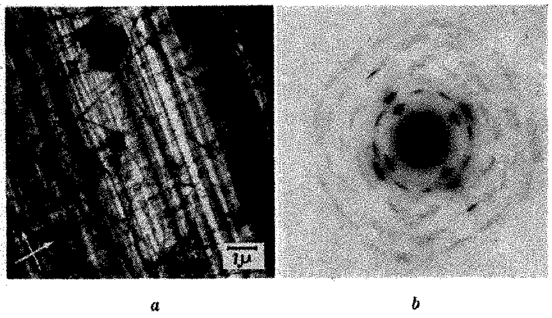
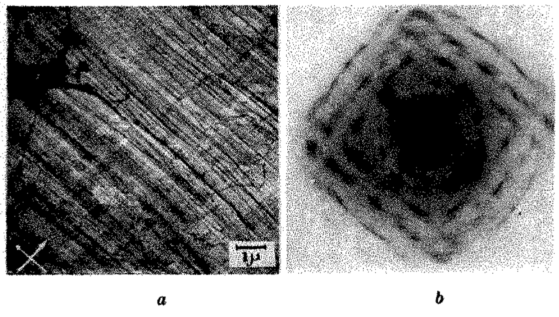
Fig. 3 reproduces the electron diffraction pattern from *Valonia* microfibril cooled to −100° C. taken by Hillier's method. This specimen was composed of a single sheet of microfibrils. It may be noted that this pattern contains a very large number of reflexions having fairly good resolution up to as high as the tenth layer line. In Fig. 3 as many as 400 reflexion spots appear, while the usual methods give at most a few score reflexions. This improvement in the diffraction pattern is considered to have resulted partly from the reduction of the thermal agitation by cooling and partly from the selection of a good crystalline part in the specimen.



a b

Fig. 1. (*a*) Electron micrograph; and (*b*) electron diffraction pattern of *Valonia* microfibril taken without cooling by Boersch–le Poole's method



a b

Fig. 2. (*a*) Electron micrograph; and (*b*) electron diffraction pattern of *Valonia* microfibril cooled to −40° C., taken by Boersch–le Poole's method

Many of the reflexions in Fig. 3 can be indexed by a monoclinic unit cell having $a = 8{\cdot}39$ A., $b = 10{\cdot}58$ A., $c = 7{\cdot}94$ A., and $\beta = 82°$, which is nearly identical to that proposed for cellulose I by Meyer and Misch[6]. These reflexions are shown by the black circles in Fig. 4, which is the projection of the reciprocal lattice in the (010)-plane. The numerical figures attached to the circles indicate the indices of the layer lines on which the reflexions appeared. It has been reported that cellobiose chains within the microfibrils of *Valonia* have a selective orientation called 'biaxial' or 'uniplanar' orientation, that is, an orientation for which not only the *b*-axis is parallel to the fibre axis but also the (101) lattice plane is parallel to the plane of the wall. The appearance of the observed reflexions can be understood if we

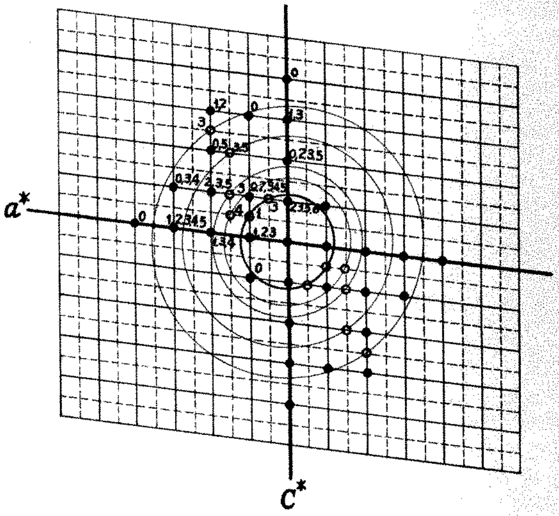


Fig. 4. (010)-Projection of reciprocal lattice. ●, Observed reflexions, which can be indexed by Meyer and Misch's unit cell; ○, super-lattice reflexions

assume that the specimen film of the microfibril was curled.

Two important points should be noted in this pattern. One point is that the reflexions (*hkl*) and ($\bar{h}\bar{k}\bar{l}$), for example, (032) and (03$\bar{2}$), have markedly different intensities. By observing the patterns for various inclinations of the specimen film around the fibre axis, it was concluded that the difference is not due to a trivial origin such as an asymmetric setting of the specimen, but rather to the difference in magnitude of the structure factors. This fact contradicts the structure of cellulose I proposed by Meyer and Misch, belonging to the space group $P_{2_1} = C^2{}_2$. The structure factor for the space group is given by

$$F_{hkl} = \begin{cases} 2\sum_j f_j \exp.(2\pi iky_j) \cos 2\pi\,(hx_j + lz_j) : k = \text{even} \\ 2i\sum_j f_j \exp.(2\pi iky_j) \sin 2\pi\,(hx_j + lz_j) : \ k = \text{odd} \end{cases}$$

by virtue of the two-fold screw axis, and would have the same magnitude for (*hkl*) and ($\bar{h}\bar{k}\bar{l}$) reflexions.

Another point to be noted in the pattern is the appearance of the reflexions indicated by the arrows (Fig. 3). They are on layer lines other than the equator. The reciprocal lattice points for these reflexions must lie upon the circles described in Fig. 4. Thus they can be indexed not by the Meyer–Misch unit cell, but by a unit cell having *a* and *c* periods twice as long as those of the Meyer–Misch unit cell.

Thus the structure appropriate for the pattern is decidedly different from the structure of cellulose I. Of course, it is different also from other structures proposed for cellulose, such as cellulose II, III and IV. It is certain that the cooling of the specimen did not influence the formation of the structure, since the reflexion characteristic of it was observed also for the specimen without cooling.

We have not yet established the details of the structure. But at least it is certain that the arrangement of cellobiose chains along the fibre axis has an order considerably different from that proposed by Meyer and Misch for cellulose I. We are not yet certain whether this structure is a new one or whether it is the correct structure for cellulose I. However, since the previous determinations of the structure of cellulose were based generally on X-ray diffraction patterns of poor resolution, their renewed examination by the new technique used above seems to be worth while.

DISTRIBUTION OF TRITIUM-LABELLED THYMIDINE IN *ESCHERICHIA COLI* DURING CELL MULTIPLICATION

By DR. R. B. PAINTER, F. FORRO, jun., and W. L. HUGHES

Medical Department, Brookhaven National Laboratory, Upton, New York, and Biophysics Department, John A. Hartford Foundation, Yale University, Valhalla, New York

CONSIDERABLE evidence[1] shows that deoxyribonucleic acid is at least one of the chemical constituents capable of carrying and transmitting genetic information in biological systems. The replication of deoxyribonucleic acid is thus an essential prerequisite to the multiplication of organisms, and fresh insight on this problem has been obtained at such widely separated points of the biological spectrum as bacteriophage by Levinthal and Thomas[2,3] and plant chromosomes by Taylor, Woods and Hughes[4]. The use of phosphorus-32 as a specific deoxyribonucleic acid label in the phage experiments was possible because the acid is probably the exclusive location of phage phosphorus[5,6]. In cellular systems, the presence of several phosphorus-rich components considerably complicates the analysis of tracer experiments. Biochemical evidence indicates the predominant fate of thymidine to be a precursor of deoxyribonucleic acid[7-9]. Plaut and Mazia[10] were the first to use this nucleoside, labelled with carbon-14, in experiments concerned with deoxyribonucleic acid replication. Recognizing the greater resolution to be expected with tritium, Taylor, Woods and Hughes[4] prepared tritium-labelled thymidine, with which they have been able to demonstrate a remarkable orderliness for the replication of the deoxyribonucleic acid of individual chromosomes in plant roots. In bacteria, the morphological organization of the acid is far from clear. Using phosphorus-32, some limits have been placed on this organization and the mode of replication of deoxyribonucleic acid in *Micrococcus cryophilus*[11] and in *Escherichia coli* B/r[12]. The availability of tritiated thymidine of suitable specific activity and of a thymine-requiring strain of *E. coli* (*Escherichia coli* 15 T-), the deficiency of which can also be satisfied by thymidine[13], made it seem useful to study the distribution of the incorporated label among the daughters of labelled cells following growth on unlabelled medium. Since the experiments almost immediately indicated a rather striking qualitative result, we felt it worth while to communicate our initial observations.

Escherichia coli 15 T- was kindly supplied by Dr. Hazel Barner. Thymidine, labelled with tritium on the pyrimidine ring, was radiochemically pure as judged by crystallization with carrier (analysis by Schwarz Laboratories, Inc., Mt. Vernon, New York, which are now supplying the material). The specific activity was approximately 2 µc./µgm. Liquid glucose-mineral medium containing 2–4 µgm./ml. of tritiated thymidine was inoculated with a log-phase culture, suitably diluted to minimize carry-over of unlabelled thymidine. Following at least 100-fold growth at 37° C. in the labelled medium, two types of

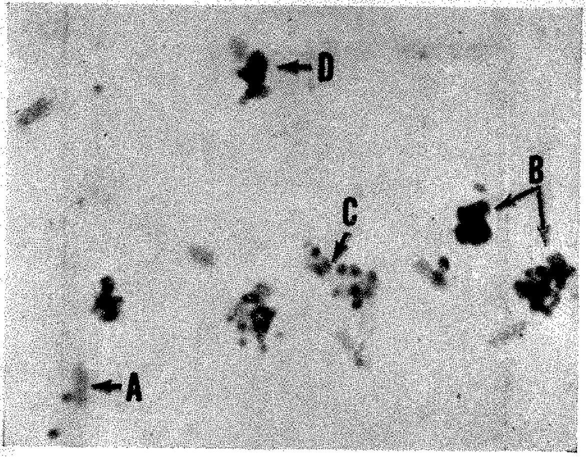

Fig. 1. Autoradiograph (× 1,600) of *E. coli* labelled with tritiated thymidine and grown in non-radioactive medium for about three generations. *A*, an example of cell showing no label; *B*, clusters of grains caused by heavily labelled cells, the grains overlying and obscuring the bacteria; *C*, an example of lightly labelled cells, where eleven individual grains can be observed over three or four cells; *D*, an example of an 'all-or-none' split, where one of a pair of cells has a cluster of grains over it, while the other has none

experiments were performed. In the first, the cells were washed in saline and grown in medium containing excess unlabelled thymidine. Direct cell counts from aliquots were taken at the time of inoculation and every 30 min. thereafter. Each time a doubling of the population of the culture occurred, as determined by the direct cell count, smears were made. These were fixed by heat, washed with water, and autoradiographs made by the stripping film technique[14]. After various exposure times, varying from 5 to 40 days, the slides were developed and stained with 0·04 per cent crystal violet. In the second type of experiment, labelled cells were isolated micromanipulatively on nutrient agar medium which contains excess unlabelled precursor. Progeny lines were obtained from these isolates, cell growth stopped by drying the agar medium, and stripping film autoradiographs made after fixing in 3 : 1 ethyl alcohol–glacial acetic acid and a series of alcohol–water solutions.

Both experiments revealed very clearly that the distribution of the incorporated tritium from the tritiated thymidine among the daughter cells grown on unlabelled medium is very heterogeneous (Fig. 1). At least as soon as the third generation and possibly sooner, one finds cells with no label in the presence of those containing considerable label. In the liquid-culture experiment, all-or-none splits, where one of an unseparated pair of cells exhibited heavy label (6–14 grains) while the other had no grains above it, were observed occasionally. Even allowing for some possible trackiness which appears to be present in the grain patterns, the magnitude and frequency of such splits made it extremely unlikely that they occur by chance. Such all-or-nothing splits are also seen in the micromanipulation experiments where the sibling relations in the progeny line are known. These micromanipulation experiments indicate that the heterogeneity observed in bulk culture experiments is not primarily a result of the death of the cell (from radiation or any other cause) and/or differences in growth-rates for individual bacteria.

Two additional comments can be made: (1) At the first division on cold medium, no case of all-or-nothing distribution has yet been seen even though attempts were made to select the smallest possible labelled cells as the sources of a progeny line. (2) Each clonal line does not show the same distribution of label. Specifically, each starting cell does not give rise to a unique number of hot cells dispersed among other cold ones; rather, the distribution of grains differs from clone to clone. In some, the distribution would be difficult to distinguish from random. In the rest, 'hot spots' and all-or-nothing splits occur at different frequencies and in patterns which still require deciphering.

The question of whether all the label is in bacterial deoxyribonucleic acid has not been completely settled. The best chemical estimates to date indicate that no less than 80 per cent is in deoxyribonucleic acid thymidine. Check experiments with two organisms not requiring thymine for growth, *Bacillus megaterium* and *Escherichia coli* B, showed that the uptake of tritiated thymidine was less than 10 per cent of that of *E. coli* 15 T-.

The observation that simple dilution of tritiated thymidine during growth does not occur would seem to indicate that relatively large amounts of parental deoxyribonucleic acid can remain functionally associated in transmission to daughter cells. It is also clear that the extent of this association of the parental deoxyribonucleic acid differs from clone to clone; that is, there is a reasonable probability of a sharing of at least some of the parental deoxyribonucleic acid between daughters at division. These results are not inconsistent with findings for deoxyribonucleic acid phosphorus-32 distribution in another bacterium[11]. Whether the functional two-strandedness of both phage and plant chromosomal deoxyribonucleic acid will be found to hold for bacteria is not clear from the results, although the lack of all-or-nothing splits at the first generation and their appearance in later generations are not in conflict with this possibility.

An exclusive model to explain these results depends, among other things, on independent information concerning the number of deoxyribonucleic acid-containing structures within a bacterium and on the quantitative aspects of the distributional patterns. We hope to report in more detail on these problems in the future.

We would like to express our thanks to Dr. J. H. Taylor for his interest and helpful discussion during the course of this work. The second author wants to express his sincere appreciation to Miss D. Patricia Frost for her excellent assistance in performing his part in these experiments.

Rate of Accretion of Cosmic Dust on the Earth

As guest professor of geophysics at the University of Hawaii, I have had opportunities for collecting cosmic dust by filtering large volumes of air through fine-pored filters at Mauna Loa Observatory on Hawaii (11,000 ft.) and from the summit of Mt. Haleakala on Maui (10,000 ft.), localities where the air is generally free from terrestrial dust to a remarkable degree. The filters were analysed for the radioactive fall-out products, strontium-89 and strontium-90, in the laboratories of the U.S. Atomic Energy Commission in New York, and for iron, nickel and cobalt in the II Chemisches Institut der Universität, Vienna. I am indebted to Mr. John H. Harley for the strontium analyses, which will be published elsewhere, and also to Prof. F. Hecht and his collaborator Dr. E. Tomic of Vienna for carrying out the analyses for the ferrides.

Of the twenty-two filters from Mt. Haleakala so far analysed for ferrides, all contained notable quantities of nickel, whereas in seven of the nine filters from Mauna Loa nickel was also found, far in excess of any possible contamination from terrestrial sources. The average weight of nickel per 1,000 m.^{3} of air passed through the filters was 14·3 μgm. as compared with 1,577 μgm. of iron, that is, a nickel to iron ratio of 0·9 per cent. Cobalt was also found in several of the filters, although in much smaller quantities than nickel, the ratio of cobalt to iron being 0·2 per cent.

The weight of cosmic dust on the filters may be estimated from the nickel content using the average amount (2·5 per cent) of nickel in meteorites of all kinds quoted by F. G. Watson[1], which gives a weight of meteoric dust of 572 μgm./1,000 m.^{3} of air.

Assuming the dust-content of cosmic origin in the atmosphere to be uniform up to the 100-km. level, for the whole atmosphere below that level a quantity of suspended dust of cosmic origin of 28·6 million tons is obtained.

In order to find from this figure a value for the annual increment of cosmic dust to the Earth, we have to assume a probable rate of descent from the 100-km. level to the 3-km. level, where the dust was collected. In the case of the finest volcanic dust from the Krakatoa eruption in 1883, according to W. J. Humphreys[2], it required about two years to settle down to the Earth's surface. With a similar rate of descent, the cosmic dust suspended in the atmosphere should be renewed in the course of two years, which makes the annual increment of such dust to the Earth equal to one half the figure given above, or 14·3 million metric tons. If more rapid renewal of the cosmic dust suspended in the atmosphere is assumed, the annual increment becomes correspondingly higher.

Comparing this figure with Van de Hulst's value[3] for the weight of the interplanetary dust giving rise to the zodiacal light and being swept up by the Earth, as 1,700 tons a day, one obtains a rate of accretion for interplanetary dust to the Earth of only a little more than 4 per cent of that for meteoric dust, or 0·62 million tons a year.

On the other hand, Watson assumes the total weight of meteoric matter reaching the Earth to be "between 1,000 or, perhaps, 10,000 tons per diem" (ref. 1, p. 94). Even with the higher of these two estimates, one finds that a total weight of 3,650,000 tons of meteoric matter should reach the Earth annually, or about one-fourth of that estimated from these experiments.

Considering the general interest for many different branches of geophysics of the rate of accretion of cosmic dust, these discrepancies call for repeated and extended experiments of this kind at other high-altitude observation posts.

Energy Spectrum of Cosmic Radiation

THE spectrum of cosmic radiation has the remarkable property that it is a power function

$$f = \text{const. } p^{-n} \qquad (1)$$

(where p is momentum), in which n has a constant value of about 2·5 for several powers of ten of p. In Fermi's theory, n is given by the ratio τ/T between the time of acceleration τ and the time of absorption (or diffusion) T. This means that the empirical formula is obtained only if one assumes that accidentally τ and T are of the same order of magnitude, and that the ratio is constant over a very wide range of momentum. Neither of these assumptions is plausible.

It is the purpose of this communication to point out that a power law can be obtained if we assume that particles, which are injected at low energies, are pumped up to higher energies by a pump, the speed of which is a power function of the momentum. No considerable loss of particles should occur during the acceleration, but when the particles have reached the maximum energy which can be stored in the accelerator, they leave the accelerator. (In this way the time of dissipation is determined by the time of acceleration.) Hence all cosmic-ray particles move up through the energy spectrum in a more or less systematic way, and the time they spend in a certain energy-range is inversely proportional to the speed of the pump.

This effect can be produced in several ways, and we shall consider a mechanism in which the betatron effect is combined with a scattering or diffusion of the particles[1]. If the magnetic field H in a certain volume U' increases, the momentum p of charged particles in the volume increases by Δp, which is proportional to p. If the particles are scattered, or diffused out of U' to an adjacent volume where H is constant, and later the field in U' returns to its initial value, the net result of the process is that a number of particles fU' have increased their momenta by

$$\Delta p = \alpha p \qquad (2)$$

where α is a constant. If the process is iterated and low-energy particles are injected at a constant rate, this leads to a power spectrum with $n = 1$.

If this process takes place in the neighbourhood of the Sun under influence of varying magnetic fields produced by solar activity (cf. ref. 1), the value of n may be changed for geometrical reasons. Particles that have gained enough energy diffuse away from the environment of the Sun and fill a volume U which we may put equal to :

$$U = \beta p^b \quad (3)$$

where β is a constant and $b = 2$ or 3 depending on the properties of the trapping field. They may be accelerated further, but at a slower rate because the average value of α decreases when the distance from the Sun increases. Hence α depends implicitly on U, and we may put :

$$\alpha = a . U^{-\nu} \quad (4)$$

A stationary state requires that the number of particles dn passing a certain momentum p is independent of p. Thus we have :

$$U f \Delta p = \text{const.}$$

or from (2), (3) and (4) :

$$f = \text{const. } p^{-n}$$

with $n = b(1 - \nu) + 1$. An agreement with the observational value $n = 2{\cdot}5$ requires $\nu = 0{\cdot}25$ for $b = 2$, or $\nu = 0{\cdot}5$ for $b = 3$.

Confinement of Charged Particles by a Magnetic Field

DIFFUSION which is caused by collisions in an ionized gas and which takes place across a magnetic field is known to be reduced by the field. The gas may be confined to a limited region, provided that particles can escape neither by motion along the field nor by drift motion across it. In the longitudinal direction, the particles may be trapped by strong field inhomogeneities[1] or simply by having the field lines closed within the gas volume.

Axially symmetrical, stationary magnetic fields **B** and electric fields **E** will be discussed in the present communication. The radius of gyration of a particle is assumed to be small and the drift velocity $\mathbf{u} = \mathbf{u}_\parallel + \mathbf{u}_\perp$ to be determined by[2] :

$$\mathbf{u}_\perp = \left(q\mathbf{E} - \mu \nabla B - m\frac{\mathrm{d}\mathbf{u}}{\mathrm{d}t}\right) \times \mathbf{B}/(qB^2) \quad (1)$$

where (‖) and (⊥) denote directions parallel with and perpendicular to **B**, q the charge, m the mass, μ the magnetic moment of the equivalent dipole representing the gyrating particle and $\mathrm{d}/\mathrm{d}t = \partial/\partial t + (\mathbf{u}.\nabla)$. We write :

$$(\mathbf{u}\cdot\nabla)\mathbf{u} = (\mathbf{u}_\parallel\cdot\nabla)\mathbf{u}_\parallel + (\mathbf{u}_\parallel\cdot\nabla)\mathbf{u}_\perp + (\mathbf{u}_\perp\cdot\nabla)\mathbf{u}_\parallel + (\mathbf{u}_\perp\cdot\nabla)\mathbf{u}_\perp \quad (2)$$

A magnetic field produced by a toroidal coil forms circles around the axis of symmetry, that is, the z-axis in a co-ordinate system (r, φ, z). Particles cannot be trapped in the field which gives rise to a drift motion in the z-direction.

Instead, a poloidal field is considered as shown in Fig. 1, where both **B** and **E** are supposed to be situated in planes through the z-axis. **E** may arise partly from ambipolar diffusion. The first and the fourth terms in the right-hand member of equation 2 give centrifugal forces in planes through the z-axis, whereas the third term as well as the second term give a contribution $\mathbf{u'}_\perp$ to the total drift velocity $\mathbf{u}_\perp$. The velocity $\mathbf{u'}_\perp$ is situated in planes through the z-axis, whereas all other contributions, $\mathbf{u}_\perp - \mathbf{u'}_\perp$, are drift motions in circles around the same axis. The motion $\mathbf{u'}_\perp$ of ions differs from that of electrons, and this may cause a separation of charge and generate an electric field. However, the drift arising from this additional field will be situated in the φ-direction, provided that the density distribution of the particles is axially symmetrical. The relative importance of $\mathbf{u'}_\perp$ is roughly estimated from equations 1 and 2 :

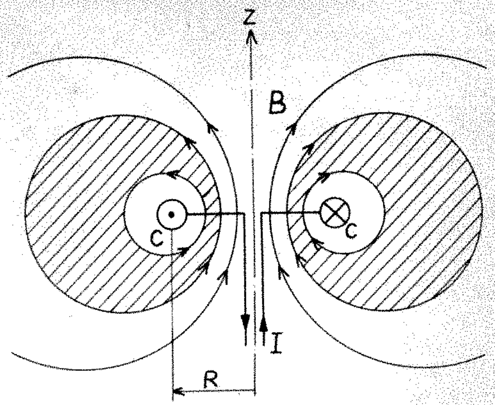

Fig. 1. The magnetic field **B** generated by a circular coil C

$$\mathbf{u'}_\perp/\mathbf{u}_\perp \approx m u_\parallel / qBR \quad (3)$$

If the gas approaches thermodynamic equilibrium, the velocity of gyration becomes comparable to $u_\parallel$, and $u'_\perp/u_\perp$ is nearly equal to the ratio between the radius of gyration and the characteristic distance R. As an example, we may choose an ionized deuterium gas at $T = 10^8$ °K. in a magnetic field $B = 30$ V.sec./m.^{2} (3×10^5 gauss) produced by a coil of radius $R = 5$ m. For ions, $u'_\perp/u_\perp$ becomes about 10^{-4} and for electrons about 10^{-6}. Even if the electric field should be as high as $V/R \approx 3 \times 10^3$ V./m., where V is the potential drop corresponding to the particle energy $3kT/2$, the drift $u'_\perp$ is not greater than 4×10^{-2} m./sec. for ions and 6×10^{-4} m./sec. for electrons. Ions will escape after about 50 sec. if only the drift $\mathbf{u'}_\perp$ is taken into account and particle interactions are neglected. Thus, a strong magnetic field is able to trap particles effectively inside a region such as that shaded in Fig. 1, at least at low gas densities.

Time variations of the magnetic field induce an electric field E_φ and a drift $\mathbf{u''}_\perp$ in planes through the z-axis, directed outwards from the coil windings when $\partial B/\partial t$ is positive. It has the magnitude :

$$|\mathbf{u''}_\perp| \approx (R/B)\cdot\left|\frac{\partial B}{\partial t}\right| \quad (4)$$

and may be regarded as a motion of matter 'frozen to' the magnetic-field lines. If B is changed by the amount ΔB during the time Δt, the displacement by the drift $\mathbf{u''}_\perp$ becomes about $R\Delta B/B$.

The magnetic field may be produced by a coil C as in Fig. 1, where the areas of the coil connexions are made as small as possible. If, in the immediate neighbourhood of the connexions, the magnetic field from the supply current predominates over the field from the coil, particles will be reflected and will not be absorbed by the connexions. The field from the supply current gives an additional drift in planes through the z-axis; but since the connexions carry current in opposite radial directions, a cancellation of the drift takes place for particles passing around the z-axis repeatedly. Further, the coil windings will have finite electric conductivity and a stationary electric field will be generated by a potential drop in the φ-direction. This field should be screened by a metal coating around the coil and its connexions.

Charged particles may be injected by sources touching the outer edge of the shaded area in Fig. 1. A slowly decreasing magnetic field may possibly produce an inward drift which prevents the particles from hitting the sources repeatedly.

Confinement at high gas densities is outside the scope of this short communication and requires more knowledge about the stability of the field, the pressure balance and the interactions between particles. The coil windings may act as a metallic wall and have some stabilizing effect on deformations of the magnetic field by motion of the gas. A particle density $n = 6 \times 10^{22}$ m.$^{-3}$, corresponding to a pressure $P \approx B^2/4\mu_0$, gives a reaction time of 15 sec. in the example above. The behaviour of a toroidal induced discharge[3] is of great interest in the present connexion.

A Travelling-Wave Parametric Amplifier

THE principle of parametric excitation of an oscillatory system has been known for many years. An electric oscillatory circuit can be excited in this way if the condenser plates are instantaneously pulled apart by a fixed amount whenever the voltage reaches a maximum value, and instantaneously restored to their original positions when the voltage is zero. Under these conditions energy is communicated to the circuit when the plates are pulled apart; but none is extracted when they are restored, and so oscillations can be maintained. The capacitance/time graph envisaged in the foregoing is a square wave at twice the resonant frequency of the circuit; but it can be shown that a sinusoidal variation at twice the resonant frequency may be used. Any method of periodically varying the capacitance may be used, or alternatively the inductance may be varied. Moreover, such a circuit can be used as an amplifier, since, at the fundamental frequency, the excitation mechanism is analogous to negative resistance.

In considering the possibility of obtaining a useful amount of parametric amplification at high radio-frequencies, a travelling-wave type of parametric excitation has been studied. It has been found that a loss-less transmission line having distributed inductance per unit length given by:

$$L = L_0[1 + \eta \sin 2(\omega t - \beta x)]$$

and constant distributed capacitance C_0 per unit length will support a growing current wave of the form

$$i = i_0 \exp(\alpha x) \sin(\omega t - \beta x + \varphi)$$

where

$$\alpha \doteqdot \omega\sqrt{L_0 C_0}.\frac{\eta}{4} \cos 2\varphi$$

$$\beta \doteqdot \omega\sqrt{L_0 C_0}\left(1 - \frac{\eta}{4} \sin 2\varphi\right)$$

If $\cos 2\varphi = 1$ the maximum possible amplification is obtained and $\alpha = \omega\sqrt{L_0 C_0}.\frac{\eta}{4}$ nepers per unit length. Under these conditions it is also found that $\beta = \omega\sqrt{L_0 C_0}$.

For example, if $\eta = 0{\cdot}1$, a gain of 1·36 db./wavelength is theoretically obtainable. However, this amplification is only obtained when the frequency ratio is precisely 2, and the correct phase relationship must be preserved if the maximum amplification is desired. Thus, the oscillator used for providing the periodic variation of inductance must be synchronized to the incoming signal.

The noise figure of such an amplifier should be very favourable, and an experimental study is being made. Related schemes, in which precise frequency and phase relationships are not demanded, are also being studied.

I am greatly indebted to Mr. I. M. Ross of the Services Electronics Research Laboratory, Harlow, for a stimulating conversation about parametric amplification.

Lattice Image of Twin Structure observed directly by Electron Microscope in a Crystal of Copper Phthalocyanine

RECENTLY, with the increase of the resolving power of the electron microscope, it has become possible to make a direct observation of a crystal lattice composed of large molecules. J. W. Menter[1] succeeded for the first time in observing the lattice structure and the edge dislocation contained in it in crystals of metal phthalocyanines. This method is also applicable to the study of the local variation of the fine structure in a crystal lattice, and the so-called selected area micro-diffraction method, when used jointly with this method, has proved its further usefulness.

As an example of such an application, we have observed directly the twin structure in the crystal lattice of the stable copper phthalocyanine, which has a lath-shaped crystal habit. It is well known that this substance has a crystal structure with space group $P\,2_1/a$ of the monoclinic system, as reported by Robertson[2], and a crystal habit in which generally the (001) plane is the largest habit surface; the crystal lath usually lies on this surface, and the b-axis coincides with the direction of the longest edge of the lath-shaped crystal. The lattice image of the $(20\bar{1})$ plane was observed by Menter with the crystal of such habit. Further investigation has shown that some crystals of the stable copper phthalocyanine frequently acquire another lath-shaped crystal habit in which the lattice plane (001) runs almost perpendicular to the flaky habit surface, which may correspond to such a plane as $(20\bar{1})$, contrary to the ordinary crystal habit. We have also taken electron micrographs of the lattice image corresponding to the (001) plane as reported in the previous paper[3]. The periodic spacing of the lattice image of the $(20\bar{1})$ plane is about 9·8 A., even when the effect of the slight inclination of the lattice plane to the surface of the usual habit is taken into consideration, while that of the (001) plane is estimated to be about 12·6 A. and is obviously larger than the spacing of the $(20\bar{1})$ plane in the ordinary crystal habit.

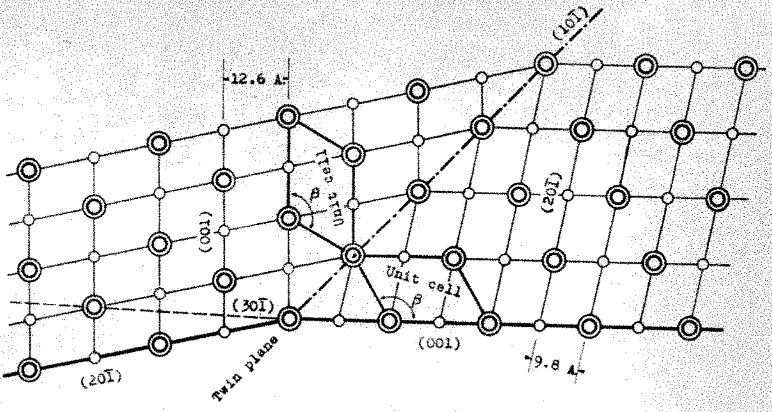

Fig. 2. Molecular configuration of the twin structure of copper phthalocyanine, projected on the *b*-plane. Small circles are at the level of $\pm \frac{1}{2} b_0$

As shown in Fig. 1, which was taken with a Hitachi electron microscope type *HU*–10, it is often observed that the lattice images of these two crystal habits are parallel and side by side, separated only with a narrow gap. The specimen used here was a stable copper phthalocyanine prepared by boiling the powder of the metastable compound with carbon tetrachloride for about 10 hr.; and it had been completely converted into the stable form. The electron micro-diffraction pattern of the selected area has two series of equidistant diffraction spots that are attributable to $(20\bar{1})$ and (001) reflexions with their higher-order reflexions superimposed on the equator, which is taken in the direction perpendicular to the *b*-axis.

We believe that such a fine structure containing the two different kinds of lattice images is due to the twin structure and is not caused by a fortuitous contact of two kinds of completely separate crystals, because the gap between the two lattices is always very narrow and has almost the same magnitude as the lattice spacing itself. Further, no contour fringe can be observed at the boundary of the two parts, even when the photograph was taken slightly out of focus so that another part of the perimeter would be bounded by the contour fringes.

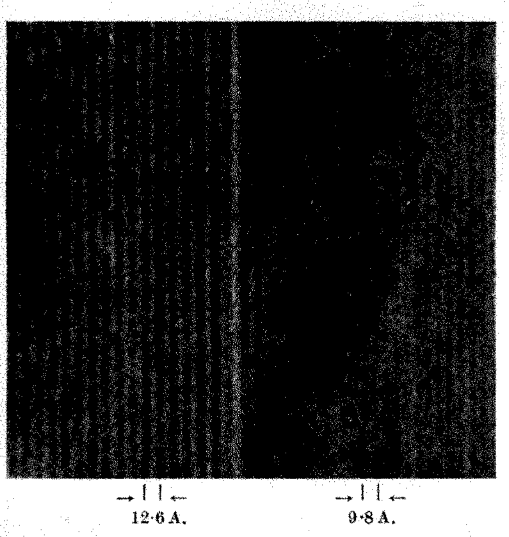

Fig. 1. Lattice image of lath-shaped copper phthalocyanine containing a twin structure

The relation between these two kinds of crystal habits and the twin structure must be considered from the point of view of the molecular arrangement. As the direction of the *b*-axis is common to the separate two parts, and the boundary is also parallel to the same axis, it is reasonable to consider that the twin plane is one of the (*h*0*l*) planes which is also parallel to the same axis. Taking the two kinds of crystal habit into consideration, the most appropriate twin plane, by which the largest habit surface of each part can be brought into a position nearly parallel to the supporting film for electron microscopy, is the $(10\bar{1})$ plane as shown in Fig. 2, in which the two kinds of the largest crystal habit surface, shown by the thick line, cross at an angle of about 14°. With this structure, the crystal can orient itself so that the incident electron beam can simultaneously satisfy the Bragg condition for both the $(20\bar{1})$ and the (001) planes, which contain an angle of about 14°; furthermore, slight relaxation of the bent crystal on the film and the elongation of the intensity region for reflexion accompanying the reciprocal lattice points (caused by the thinness of the lath crystal itself), give the reflexions from the two parts at the same time, thus enabling the lattice image of the twin structure to be observed by the electron microscope. As shown by the broken line in Fig. 2, if the $(30\bar{1})$ plane, in place of the $(20\bar{1})$ plane, is taken as the largest crystal habit surface for the part where the (001) plane runs perpendicularly to the habit surface, the flaky surface of the crystal lath becomes approximately flat as a whole. But the possibility of such structure is considered to be rather small, because the molecular density in the lattice plane of the outer crystal habit surface becomes extraordinarily small compared with the former structure.

Density of Water sorbed on Montmorillonite

In a recent communication, Anderson and Low[1] have described some investigations indicating that the water present in Wyoming bentonite (montmorillonite) pastes has a density lower than that of liquid water. It should be noted, however, that this does not preclude the water sorbed in the primary process having a close-packed structure around the ions[2], and consequently having a much higher density. For example, for monovalent or divalent ions the amount of such water would only be some 4 or 12 molecules, respectively, per ion, and if the additional sorbed water were considered to have, say, the hexagonal-net structure[3], the density of which would be about 0·9, the value for the density of the sorbed water would drop rapidly at water contents above about 7–10 per cent, and for pastes with 60 per cent water[1] could easily be less than unity. Such a decrease in density of sorbed water is well shown by the results of De Wit and Arens[4], who obtained values as high as 1·41 at 11·6 per cent moisture, dropping to 0·997 above 30 per cent. Somewhat similar results were obtained in this Institute some time ago using a density-bottle technique with a specially devised de-airing procedure and 'Dekalin' as the non-sorbed liquid. Values ranging from about 1·38 at 9 per cent water to about 1·06 at 20 per cent water were obtained—in substantial agreement with the results of De Wit and Arens[4].

The validity of any results for the density of sorbed water are, however, extremely difficult to assess, since every value must necessarily involve the volume of the sorbed water, and this has to be estimated on the assumption that the amount of swelling of the mineral represents the volume of this water. Irrespective of water content, this can only be true if the surfaces of the individual mineral layers are impermeable. It is well known, however, that the layer surfaces of montmorillonite are not continuous but consist of a hexagonal network of oxygen ions with holes of approximate radius 1·3 A. On complete removal of water, ions can, at least partially, fit into these holes. Furthermore, recent unpublished work with montmorillonite saturated with various cations suggests that the oxygen ions of UO_2^{2+} may, to some extent, fit into the holes when the mineral is in the collapsed condition (cf. the results of Nuss and Wey[5]). It is reasonable, therefore, to suppose that at least some water molecules may find their way into such holes, and thus have an apparent density approaching infinity. This factor would influence results whether clay pastes or clay powders are used, and all results must be influenced thereby. It is not possible at present to determine the magnitude of error likely to arise from this cause, or even to decide whether it is appreciable. The fact that montmorillonite equilibrated at 0 per cent relative humidity has, according to De Wit and Arens[4], a higher density than clay oven-dried to 0·0 per cent moisture, cannot be used as an estimate of the size of the effect, since (although no details are given) it is likely that the oven-drying was carried out at 105° C. when a few per cent of sorbed water was still present. In the results obtained at this Institute drying at 190° C. was employed.

Another factor only operative at low water contents is the assumption that the layers are sufficiently flexible to fit closely around the interlayer water 'islands'. Any departure from this condition would tend to act in the opposite way from the above effect and give low values. The magnitude of the error likely to arise from this factor is also unknown, but the two opposing tendencies cannot balance since this error becomes less the higher the proportion of water.

From the above considerations, it would appear that no very useful conclusions regarding interlayer water configuration can yet be drawn from density measurements.

Amino-acids in Anthracite

A topic of current interest in palæo-biochemistry is the demonstration of chemical constituents in fossils from the earliest plant and animal life. It has been shown that bones of great archæological age may contain appreciable amounts of organic nitrogen[1,2]. Even such highly organized compounds as amino-acids have been identified in fossil shells and bones[3].

As a contribution to these investigations, it seemed worth while to analyse the protein remains in anthracite—one of the oldest fossils known.

The central part of a thoroughly rinsed piece of anthracite from a British mine was ground into a powder in a mortar. After drying, 100-mgm. aliquots of the powder were hydrolysed in ampoules with 6 *N* hydrochloric acid for 24 hr. at 100° C. The hydrochloric acid was afterwards removed by means of freeze-drying. The residue was dissolved in distilled water, filtered to remove coal particles and evaporated *in vacuo* to dryness. The residue was redissolved in 0·2 ml. of distilled water. 100 µl. of the solution were applied to paper sheets (Whatman No. 4) for two-dimensional chromatography in phenol and colloidin–water systems according to Dent[4]. The amino-acid spots revealed with ninhydrin were allowed to develop for 24 hr. in the dark and preserved by treatment with a solution of cupric nitrate in ethanol. The semi-quantitative estimations of the amino-acid content of the spots were made according to Dent[4]. The α-amino-nitrogen content was determined by a method suggested by Woiwod[5].

After two-dimensional paper chromatography, aspartic acid, glutamic acid and glycine could be demonstrated in the coal samples. The semi-quantitative estimation showed a relative proportion of 12 per cent aspartic acid, 40 per cent glutamic acid and 48 per cent glycine. The α-amino-nitrogen content was 0·12 per cent, which roughly corresponds to 1 per cent of amino-acids in the original anthracite sample.

Amino-acids have thus been demonstrated in fossils about 250 million years old. Because of the procedure used for the preparation, it is impossible to tell whether these amino-acids are free or the result of the hydrolysis of peptides, though it is highly probable that the source of the amino-acids was the original proteins. We cannot, however, give any satisfactory explanation as to why only these three amino-acids, namely, aspartic acid, glutamic acid and glycine, were left unchanged by time, but it is interesting in this connexion to note that Ezra and Cook[6] recently reported the finding of these three amino-acids in fossil bones some thousand years old. Abelson[3] demonstrated the same three amino-acids, together with alanine, leucine and valine, in a fossil of Devonian age.

It is furthermore tempting to correlate our results with those of Chen and Rickenbacher[7], who found traces of aspartic acid and glutamic acid in amphibian eggs. Not until in the gastrula and blastula stages did the rest of the amino-acids appear.

These investigations thus suggest that aspartic acid, glutamic acid and glycine are among the first amino-acids to be formed and the last to be decomposed in living organisms.

Small-Scale Preparation of Glyoxylic Acid labelled with Carbon-14

During the course of a study of glyoxylic acid metabolism in wheat it became desirable to obtain glyoxylate labelled with carbon-14, a compound which does not appear to be available commercially. Oxalic acid, which is available commercially as oxalic acid-^{14}C, has been used in the synthesis of glyoxylic acid[1–4]. Weinhouse and Friedmann[5] synthesized glyoxylate-^{14}C from oxalate-^{14}C by reduction with mercuric chloride and Grignard magnesium. In order to isolate the crystalline bisulphite addition product of glyoxylate it was necessary to dilute the oxalate-^{14}C (2·25 mgm.) with 900 mgm. of inactive oxalate. Tafel and co-workers[3,4] introduced an electrolytic method for the reduction of oxalate to glyoxylate. These workers used relatively large amounts of oxalate (10 gm.) and obtained very high yields (87 per cent). The reaction was carried out in 10 per cent sulphuric acid at 10° C. with a current of 4 amp. and was complete in 30 min. Mohrschulz[2] investigated the reaction more thoroughly and showed that it could be carried out in 2 per cent sulphuric acid at a temperature of 15–20° C. The highest yields were obtained using mercury as the cathode (rather than lead, copper or nickel).

We have found it possible to extend the electrolytic method to the reduction of milligram quantities of oxalate and have obtained high yields of glyoxylate. The electrolysis apparatus (Fig. 1) consists of a vessel 1·4 cm. in diameter and 2·4 cm. high containing 1 ml. of mercury, a 4½-volt dry-cell battery, and two 26-gauge platinum electrodes.

0·1 ml. of 2 per cent sulphuric acid containing 0·14–3 mgm. of oxalic acid is pipetted into the beaker to form a peripheral layer into which dips the anode. The cathode leads through a short length of glass tubing (diam. 5 mm.) into the mercury.

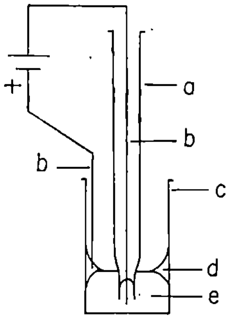

Fig. 1. Electrolysis apparatus used in the reduction of oxalic acid: *a*, glass tube; *b*, 26-gauge platinum electrode; *c*, glass beaker, diameter 1·4 cm.; *d*, reaction mixture; *e*, mercury cathode. Power source is a 4½-V. dry cell

The effects of the quantity of oxalate and of the reaction time on the yield of glyoxylic acid were studied. Some results are shown in Table 1. Glyoxylic acid was determined quantitatively as its 2,4-dinitrophenylhydrazone. The reaction products were treated with a slight excess of 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid and the mixture extracted into ethyl acetate. The ethyl acetate extract was washed with ethyl acetate, made to volume and its density determined spectrophotometrically at 368 mμ using a Beckman model *DU* spectrophotometer.

Glyoxylic acid 2,4-dinitrophenylhydrazone was identified by paper chromatography[6]. This compound gives two spots on chromatograms which are recognizable by their R_F values and by their characteristic colour reaction with ethanolic sodium hydroxide.

With 0·7 mgm. of oxalic acid a reaction time of 10 min. was found to be very satisfactory. After a number of trials with inactive oxalate which gave consistently high yields (about 95 per cent), radioactive oxalate was used. 0·7 mgm. oxalic acid-^{14}C (26·5 μc./mgm.) in 0·1 ml. of 2 per cent sulphuric acid was electrolysed for 10 min. and the reaction solution was chromatographed in one direction on Whatman No. 1 paper by the ascending method, using chloroform/95 per cent ethanol, 1/1 + 2 per cent (v/v) formic acid[7] as solvent. In this solvent system the R_F values of oxalic and of glyoxylic acids are 0·06 and 0·80 respectively. Counting the radioactivity directly on the paper showed approximately 95 per cent of the activity in glyoxylate, 3 per cent in oxalate and 2 per cent in an unidentified band of R_F 0·9. The identity of the zone corresponding to glyoxylate was verified by elution of the band with water, and reaction of the eluate with 2,4-dinitrophenylhydrazine followed by paper chromatography. In addition, the 2,4-dinitrophenylhydrazone was hydrogenated, and the resulting radioactive glycine identified with two-directional paper chromatography[8].

The advantages of this method for preparing glyoxylic acid-^{14}C are that it is simple, rapid and inexpensive. Because it is suitable for use with small

Distribution of Carbon-14 in Labelled Amino-acids separated on Paper Chromatograms

An important problem in the biochemical application of the labelled pool technique is the determination of the uniformity of labelling of compounds separated on paper chromatograms in amounts below the limits of chemical detection[1].

The use of ninhydrin (triketohydrindene hydrate) as a spray[2] or, preferably, as an acetone dip[3] for the detection of α-amino-acids separated on paper chromatograms, is well established. The reaction involves a quantitative oxidative deamination of the α-amino-acid according to the equation[4-6]:

$$R.\mathrm{CH(NH_2).COOH} + \cdot\mathrm{O} = R.\mathrm{CHO} + \mathrm{NH_3} + \mathrm{CO_2}$$

The loss of radioactivity from an α-amino-acid separated on a paper chromatogram, as a result of treating it with ninhydrin, might then be expected to indicate the proportion of carbon-14 in the carboxyl group of the acid. This was found not to be the case in practice because of the volatility of the labelled aldehyde also produced, and because decarboxylation only appeared to be quantitative under the right conditions of time, temperature and relative humidity. The effect of relative humidity on the ninhydrin colour reaction has been noted by other authors[7].

The simple method described below was developed for application to α-amino-acids labelled with carbon-14 separated on paper chromatograms and has given reproducible results with known labelled acids as shown in Table 1.

The low recoveries of carbon-14 dioxide from the 1-^{14}C-glutamate are not understood but do not appear to be explained by the presence of carbon-14 in groups other than the 1-carboxyl (see below). The proportions of carbon-14 in the 1-carboxyl group of the labelled amino-acids was confirmed by measuring the specific activity of the $^{14}CO_2$ liberated from carrier-diluted samples on the semi-micro scale by an adaptation of the Van Slyke method[4,5]. These results are shown in Table 2. Doubts earlier expressed[8] on the uniformity of labelling of amino-acids from *Chlorella* grown on $^{14}CO_2$ as sole carbon source are now believed to be unfounded (Catch, J. R., personal communication).

Table 1. NINHYDRIN DECARBOXYLATION OF AMINO-ACIDS LABELLED WITH CARBON-14 ON PAPER

* Uniformly labelled acids prepared from *Chlorella* grown in $^{14}CO_2$ as sole carbon source.

The apparatus consists of a 15 cm. × 1·5 cm. 'Pyrex' tube provided with a *B* 14 standard head and vacuum tap as illustrated (Fig. 1). Aqueous sodium hydroxide (40 µl. of 1 *N* solution) is micro-pipetted on to a 2-cm. circle of Whatman No. 1 paper, dried in a warm air stream, and gently pushed into position *A* of the tube. A plug of glass wool washed with hydrochloric acid is inserted at *B* followed by a 1-cm. layer of granular activated charcoal at *C*. Four or five drops of distilled water are placed on the charcoal. A 2-cm. circular sample of the labelled amino-acid zone (located by scanning[1]) is removed from the Whatman No. 1 paper chromatogram by means of a suitable cork-borer. It is weighed and assayed for activity of carbon-14 under a thin end-window Geiger–Müller tube by mounting under rigid and reproducible geometrical conditions and taking the mean of pairs of counts made over both faces of the sample. The sample should not contain more than 50 µgm. of the amino-acid. The sample is briefly dipped in a 0·5 per cent (w/v) solution of ninhydrin in acetone (analytical reagent), quickly dried, and pushed into position *D* of the tube. The *B* 14 head is immediately placed in position, the tube pumped out to approximately 30 cm. of mercury pressure, and the tube warmed in an oven at 90–95° C. for 2 hr. The tube is next allowed to cool for a further hour at room temperature. The alkaline paper circle is then

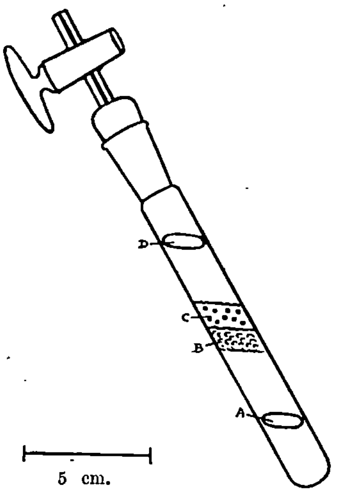

Fig. 1

removed, weighed, and assayed for activity of carbon-14 as above. Self-absorption corrections are made if the weights per unit area of the circles differ significantly[9]. The water in the tube provides the necessary moisture for the reaction, and the activated charcoal selectively absorbs any labelled volatile aldehyde formed. The proportion of the original activity of carbon-14 recovered on the alkaline circle represents the proportion of the carbon-14 present in the 1-carboxyl group. The method provides a simple test for the uniformity of labelling of α-amino-acids.

Absorption Spectra of Molecular Complexes

It has been shown by several workers[1-4] that there is a rough correlation between the lowest ionization potential of an electron donor and the frequency of the maximum of the charge-transfer band (ν_{CT}) of lowest energy characteristic of the complex of the donor with a given acceptor. That the relation is not a very strict one is illustrated by Fig. 1, where such a plot is given for chloranil complexes in solution in carbon tetrachloride. The ionization potentials are those measured by Watanabe[5] using a photo-ionization method.

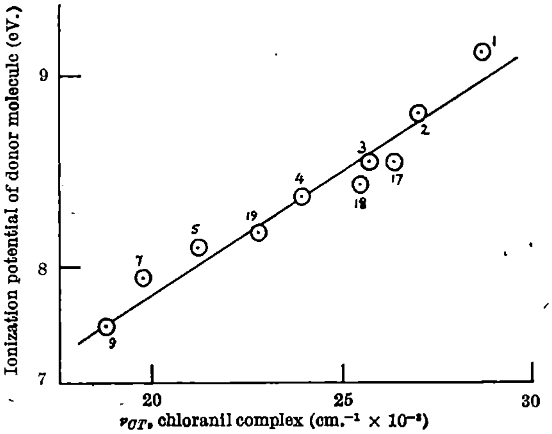

Fig. 1. The relation between the ionization potential of the donor molecule and ν_{CT} of the corresponding chloranil complexes in carbon tetrachloride

However, the plot of ν_{CT} for a series of complexes of electron donors with a particular acceptor against ν_{CT} for the same series of donors with a second acceptor shows a much closer correlation. Examples of such plots are given in Fig. 2. The values of ν_{CT} for the iodine and iodine monochloride complexes are those obtained by Keefer and Andrews[3] and de Maine[6]. It was not possible to assign a reliable value to ν_{CT} for the chloranil–durene complex, because of the skew nature of the absorption band. The solvent in all cases was carbon tetrachloride. To change the solvent to *cyclo*hexane increases ν_{CT} for the chloranil

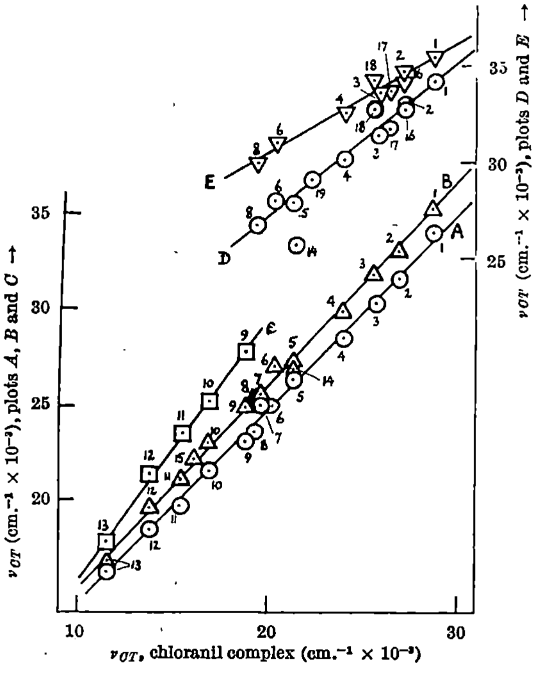

Fig. 2. The relation between ν_{CT} of chloranil complexes and ν_{CT} of complexes involving (*A*) *p*-benzoquinone; (*B*) *s*-trinitrobenzene; (*C*) *s*-trinitrotoluene; (*D*) iodine; (*E*) iodine monochloride. The numbers in the figures refer to the donor molecules: (1) benzene; (2) toluene; (3) *m*-xylene; (4) mesitylene; (5) naphthalene; (6) pentamethylbenzene; (7) 1-methylnaphthalene; (8) hexamethylbenzene; (9) aniline; (10) N-methylaniline; (11) N:N-dimethylaniline; (12) tetrabase; (13) N:N:N′:N′-tetramethyl-*p*-phenylenediamine; (14) phenanthrene; (15) anthracene; (16) dibenzyl; (17) *o*-xylene; (18) *p*-xylene; (19) anisole

complexes by about 300 cm.$^{-1}$, but a change of solvent to *cyclo*hexane or to chloroform[4] has little general effect in the case of the *s*-trinitrobenzene complexes.

The correlations in the case of the iodine monochloride and iodine complexes are not so close. In particular it would appear that the value of ν_{CT} for the naphthalene–iodine monochloride measured by Keefer and Andrews[2] is very high. Some of these variations may be due to differences arising from the perpendicular orientation of the acceptor in the complexes involving halogen molecules and the parallel orientation when the acceptor molecule is an aromatic or a quinone.

It may be noted that the variation of ν_{CT} with changing donor molecule is less in the complexes with iodine monochloride than in the complexes with iodine. This might be expected, as iodine monochloride is the weaker Lewis acid of the two. The reverse appears to hold, however, in the case of the *s*-trinitrotoluene and *s*-trinitrobenzene complexes, where *s*-trinitrotoluene is the weaker Lewis acid.

This work was carried out during the tenure of an Edward A. Deeds Fellowship of the University of St. Andrews.

Adsorption Chromatography on Silica-treated Paper

PAPER partition chromatography is not successful with many organic compounds for two reasons: (1) the compounds have low solubility in water, and hence move on the solvent front in normal partition systems; (2) low reactivity of the compounds makes detection of the position of spots difficult.

To overcome the first of the difficulties, methods have been described which employ an organic solvent as the stationary phase on the chromatogram[1–3]. Alternatively, adsorption chromatography may be used instead of partition chromatography[4]. Also, Kirchner and Keller[5] have described the use of silica-treated paper for chromatography of dinitrophenylhydrazones.

The method here described has the convenience of paper chromatography, and may be used for a wide range of compounds difficult to chromatograph by partition methods. The chromatograms are run, with the solvents normally used in adsorption chromatography, on filter paper which contains approximately 20 per cent (w/w) of silica. Unreactive compounds are detected by the blue colour of the starch–iodine reaction, while other more reactive compounds may be detected by their own specific reactions.

The silica-treated paper is prepared as follows. Sheets of Whatman No. 1 filter paper (24 in. × 8 in. has been found a convenient size to handle) are passed slowly through a 25 per cent (w/v) solution of commercial sodium silicate in water and hung up to drain for approximately 30 min. It is essential that the paper is not allowed to dry at this stage. The papers are then passed slowly through a 3 *N* hydrochloric acid bath, and once again allowed to drain for 30 min. After draining, the papers are washed in running tap water for 2 hr. and finally hung up to dry overnight. Heating the dry paper in the oven at 100° C. for 15–30 min. before use activates the silica considerably, and produces better resolution on the chromatograms.

The mixture to be chromatographed is spotted on the paper in the usual way. It is preferable to use a volatile solvent for applying the mixture, as the applied spot must be free from moisture before the paper is placed in the chromatography tank. Chromatograms are developed by the ascending-flow method, in tightly sealed jars lined with filter paper saturated with the solvent. (Battery jars with ground-glass edges have been found suitable.) Light petroleum (b.p., 40–60° C.), benzene and chloroform have been found to be the most useful solvents for development of the chromatograms. The solvent front is allowed to ascend about 10–15 cm. before the chromatograms are removed.

Unreactive compounds are detected by dipping the dry chromatograms in a solution of iodine (1·5 per cent) in carbon tetrachloride, and allowing excess iodine to evaporate off the paper. A stream of air is useful in hastening this process. Compounds then show up as brown spots on a white background[6]. The spots may be intensified by dipping the iodine-treated chromatogram in 1 per cent starch solution, when blue spots of greater intensity are obtained. Any background of blue due to residual iodine may be removed by a brief exposure to sulphur dioxide gas.

The method has been successfully applied to the separation of many types of organic compounds, including terpenes, leaf pigments, phenolic ethers and esters, and steroids.

I am indebted to Dr. W. G. C. Forsyth, director of the Colonial Microbiological Research Institute, for helpful advice, and to the Colonial Products Council for permission to publish this communication.

Thermocell with Ion-exchange Polymer Electrolyte

RECENT communications[1,2] have described some thermocells in which two electrolyte solutions in contact with reversible electrodes are separated by an ion-exchange resin barrier. The ion-exchange resin in our apparatus is the sole electrolyte in physical contact with two identical copper electrodes and behaves as a solid electrolyte. The theoretical development of thermocells[3] is then applicable in an especially simple form.

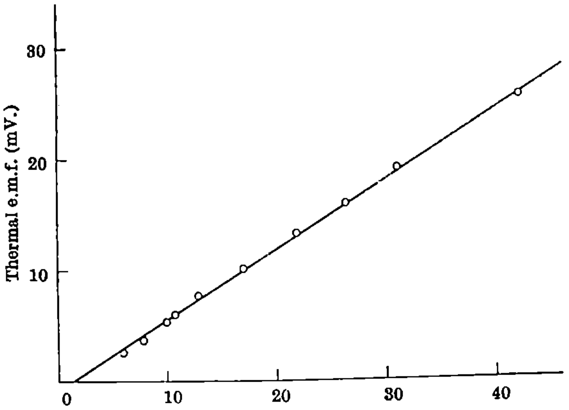

Fig. 1. Thermal electromotive force *vs.* temperature difference for the thermocell $(t)\mathrm{Cu/Cu^{2+}}$ ion-exchange resin/$\mathrm{Cu}(t + \Delta t)$, where $t = 2{\cdot}5 \pm 2{\cdot}5°$ C. The cell dimensions are: *A*, 12 cm.^{2}; *d*, 0·07 cm. The cold electrode is the anode; the electrolyte is saturated with water

The cell was constructed by pressing the ion-exchange resin in the form of a flat sheet between machined surfaces of copper. The electrolyte itself was an ion-exchange membrane, 'Nepton' *CR*–51 (unbacked type, Ionics, Inc., Cambridge, Mass.), consisting of a condensation polymer of phenol sulphonic acid and formaldehyde. This membrane had been converted into the leached copper-ion state by equilibration in five successive 2 *N* copper sulphate solutions of 100 times the membrane volume followed by long rinsing in distilled water. It is presumed that the membrane thus prepared contains copper ions in such amount that their charges exactly compensate the fixed negative sulphonate groups on the polymeric matrix. The transference number of copper ions in this electrolyte is unity.

The massive copper plate electrodes were maintained in intimate thermal contact with a stream of water at various controlled temperatures on the hot side and a rapidly stirred water-ice bath on the cold side. Measurement of Δt was accomplished by means of a differential copper-constantan thermocouple. The thermocell potentials were measured using an accurate potentiometer to the nearest 0·1 mV.

The results of three sets of measurements employing different samples of the ion-exchange polymer have yielded values 0·59, 0·64 and 0·65 mV./°C. (average 0·63) for the thermal electromotive force of the cell. A typical set of results is shown in Fig. 1. The relation between potential and temperature difference is linear, but extrapolation reveals a small dissymmetry potential which may be caused by inhomogeneity in the ion-exchange resin.

The Soret effect for copper ions appears to be entirely prevented by the nature of the electrolyte, but diffusion of water under the influence of the thermal gradient can occur.

The present results are consistent with other information. It has been reported[5] that a copper thermocell containing an aqueous copper sulphate electrolyte (0·94 *M*) had a thermoelectric power of 0·96 mV./°C. with the high-temperature electrode as the cathode. The temperature coefficient of the ($\mathrm{Cu} \rightarrow \mathrm{Cu^{2}+} + 2e-$) half-cell has recently been reported[6] to have the value −0·81 mV./°C. for copper solutions of unit activity and independent of the nature of the anion. Our results probably are indicative of an activity of copper ions less than unity. Holtan's treatment of thermocells could be applied to the present case if further information on the water transported by copper-ion migration[6] and the activity of copper ions in the ion exchanger were available. Evidence that the copper–copper ion-exchange membrane half-cells are probably reversible has already been obtained and will be reported elsewhere. Such ion-exchange thermocells may have some practical application as a temperature-sensing device.

I am indebted to Dr. H. A. Liebhafsky of this Laboratory for suggesting this type of ion-exchange thermocell.

Synthesis of Succinate from Acetate by an Enzyme System of Pig Heart Muscle

The oxidation and condensation of two molecules of acetate to form succinate was first proposed by Thunberg[1]. Many later attempts have been made to demonstrate this reaction, with for the most part equivocal results. Recently, evidence has been presented[2] that the reaction does not occur in *E. coli*. On the other hand, evidence has been presented[3,4] that extracts of *Tetrahymena* catalyse the Thunberg reaction at a slow rate, and Seaman[5] has presented evidence that mammalian tissue catalyses the reduction of succinate to acetyl coenzyme A.

This report presents evidence that an enzyme system present in pig heart muscle catalyses the oxidation and condensation of acetate to form succinate.

The enzyme was prepared by extracting an acetone-dried powder of pig heart muscle with potassium phosphate buffer (0·1 *M*, *p*H 7·4) and fractionating with ammonium sulphate. The protein precipitated between 30 and 65 per cent saturation was dissolved in the minimum volume of potassium phosphate buffer (0·1 *M*, *p*H 8·0) and stored in the deep freeze at −18°. Activity was retained for at least four months.

When the enzyme was incubated under anaerobic conditions with acetate-2-^{14}C, adenosine triphosphate, magnesium, coenzyme A and glutathione, a number of radioactive spots were obtained (Fig. 1). Some of the compounds have been identified as S-acetyl-coenzyme A and S-acetyl glutathione, but the compound with an R_F of 0·55 in butanol/formic acid/water has not yet been identified. The radioactive compound with the highest R_F was identified as succinate by the following criteria: (1) Chromatography and co-chromatography in the following solvents: butanol/formic acid/water; tertiary amyl alcohol/formic acid/water; propanol/ammonia/water; ethanol/ammonia/water and phenol. (2) Two dimensional co-chromatography in tertiary amyl alcohol/formic acid/water and ethanol/ammonia/water. (3) Oxidation by succinoxidase prepared from pigeon breast muscle. The products of the oxidation were identified as fumarate and malate (Fig. 2).

The radioactivity incorporated into succinate is small, but is increased several-fold by the addition of oxidized glutathione or acetaldehyde diphosphopyridine nucleotide and alcohol-dehydrogenase to serve as hydrogen acceptors (Table 1).

Table 1. EFFECT OF HYDROGEN ACCEPTING SYSTEMS ON THE FORMATION OF SUCCINATE FROM ACETATE-2-^{14}C. REACTION MIXTURE AS IN FIG. 1. INCUBATION AT 30° FOR 2·5 HR.

Conditions	Counts per min. in succinate
No additions	1,560
Oxidized glutathione 10 μmoles	5,800
Oxidized glutathione 10 μmoles Acetaldehyde 20 μmoles, coenzyme I 0·1 μmole, alcohol dehydrogenase 0·1 mgm.	7,220

The physiological significance of the enzyme system is uncertain. The very slow rate of succinate formation from acetate (0·07 μmole succinate/hour/10 mgm. protein) agrees with the results of Seaman, who suggests that the enzyme may function by splitting succinate. However, many biological dehydrogenations are driven against an energy barrier by coupling to the electron transporting system. Consequently, coupling the Thunberg condensation to the electron transporting system should increase the formation of succinate. Preliminary experiments with pigeon liver mitochondria show that when succinate oxidation is blocked by malonate there is a 10 per cent incorporation of acetate in succinate. It is thus possible that, in the conversion of fats to carbohydrates[6], the Thunberg condensation serves as an alternative reaction to that catalysed by malate synthetase[7]. In this context it is perhaps relevant that malate synthetase has not been demonstrated in animals[8].

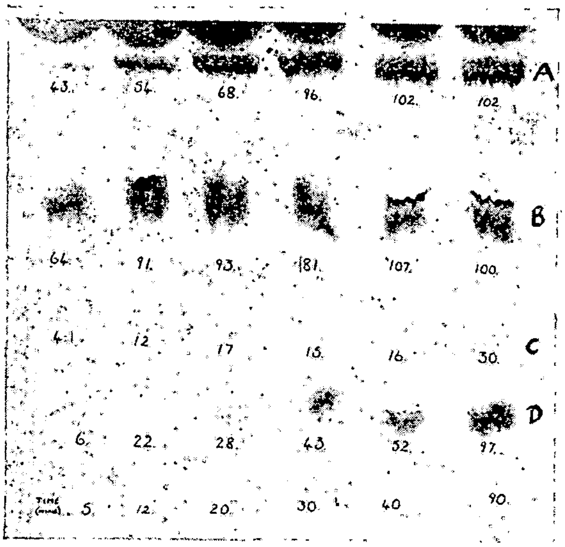

Fig. 1. Radiochromatogram demonstrating the formation of succinate from acetate-2-^{14}C. Reaction mixture potassium acetate (10 μmoles), acetate-2-^{14}C (10^5 counts per min.), magnesium chloride (5 μmoles), adenosine triphosphate (10 μmoles), glutathione (50 μmoles), coenzyme A (0·1 μmole), *tris* buffer *p*H 8·0 (0·1 *M*), enzyme (0·2 ml.), total volume 2 ml. Anaerobic conditions, bath temperature 35°. Samples (0·2 ml.) removed at times indicated and after removal of protein applied to filter paper chromatograph and run in butanol/formic acid/water. Figures under radioactive areas give counts per min. *A*, Acetyl coenzyme A; *B*, acetylglutathione; *C*, unknown; *D*, succinate

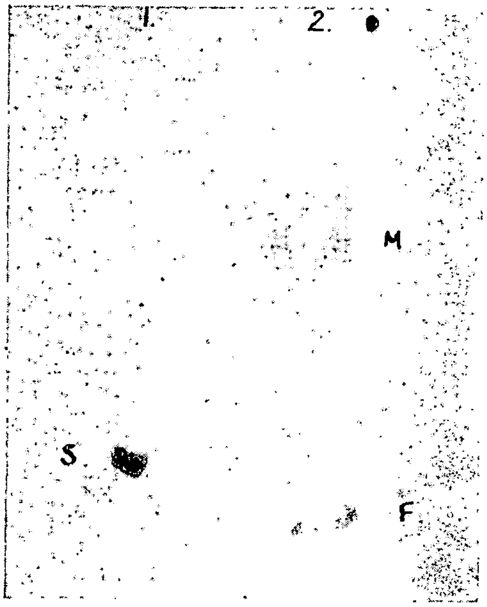

Fig. 2. Radiochromatogram demonstrating that the radioactive compound, identified as succinate, gives fumarate and malate labelled with carbon-14 after oxidation with succinoxidase. Line 1, Succinate before oxidation; line 2, products after oxidation with succinoxidase. Solvent system tertiary amyl alcohol/formic acid/water. *M*, Malate; *S*, succinate; *F*, fumarate

N-Terminal Amino-acids of Bovine Eye Lens Proteins

THE proteins of the crystalline lens are of particular significance to the embryologist because of the (serological) organ specificity of this part of the eye. In connexion with other biochemical and serological studies in our laboratory an investigation is being made on the N-terminal amino-acids of the main lens proteins: α-, β- and γ-crystallin. The preparations of α-crystallin have been isolated mainly by zone electrophoresis on starch[1]. They showed one single peak in both paper electrophoresis and moving-boundary electrophoresis at *p*H 4·2; 6·2; 7·1; 7·8; and 8·9 respectively. In the ultracentrifuge only a very small percentage of impurities was still noticeable. Some preliminary experiments were also made on β- and γ-crystallin, which preparations were obtained by salting out with ammonium sulphate and still showed small amounts of impurities when investigated by electrophoresis and ultracentrifugation.

For the end-group determinations Sanger's dinitrofluorobenzene method, as described by Fraenkel-

Conrat, Harris and Levy[2] was mainly used. The dialysed and freeze-dried proteins were dissolved in portions of 200 mgm. in 9 ml. water, and 300 mgm. dinitrofluorobenzene in 6 ml. ethanol added. The mixture was kept at pH 8·1 with 0·05 N sodium hydroxide added by means of an autotitrator. From the alkali uptake during the reaction it was found that, at room temperature, a period of 7 hr. was necessary for completing the reaction with α-crystallin. The dinitrophenyl–protein remained in solution ; spectrophotometric analysis prior to hydrolysis showed dinitrophenyl–proline and –hydroxyproline to be absent. By using performic acid oxidation cystine could also be excluded as N-terminal amino-acid.

After precipitation with hydrochloric acid, the dinitrophenyl–α-crystallin was washed out as usual with water, ethanol, ether and ethyl acetate to ensure a complete removal of dinitrophenyl–peptides that might be present together with salts and excess reagent. Hydrolysis was carried out by heating at 110° C. with 5·7 N hydrochloric acid in sealed evacuated tubes for 8 hr. For the determination of dinitrophenyl–ε-lysine a hydrolysis time of 72 hr. was necessary.

For paper chromatography Whatman No. 52 paper was used.

In the water-soluble fraction of the hydrolysate only dinitrophenyl–ε-lysine was present, in a quantity of 21 moles per 100,000 gm. dinitrophenyl–α-crystallin. In the ether-soluble fraction the following dinitrophenyl–amino-acids were found in α-crystallin (Table 1).

Table 1. N-TERMINAL AMINO-ACIDS IN α-CRYSTALLIN

Dinitrophenyl-amino-acid	R_F*	R_F†	Mol. dinitrophenyl-amino-acid per 100,000 gm. dinitrophenyl-protein‡
Glutamic acid	0·01	0·49	1·00
Serine	0·12	0·43	0·12
Glycine	0·18	0·27	0·07
Alanine	0·27	0·37	0·05
Threonine	0·18	0·42	0·02

* R_F toluene system of Biserte *et al.*, as modified by Levy (ref. 3).
† R_F phosphate buffer (Levy, ref. 3).
‡ Corrected for losses during the procedure.

The very small quantities of dinitrophenyl derivatives of serine, glycine, alanine and threonine may represent either impurities still present in the preparations or terminal groups resulting from partial breakdown of the peptide chain.

An interesting result of the preliminary experiments on the other fractions, β- and γ-crystallin, was that the same N-terminal amino-acids (mainly glutamic acid) were found to be present, although in different proportions. This might be an expression of organ specificity of these proteins. The experiments are being continued.

We are grateful to Prof. H. Gerding for his interest and critical discussions ; thanks are also due to Dr. W. F. Bon for carrying out the ultracentrifuge experiments and to Mr. H. P. Wijnand for assistance with electrophoresis.

A Histoautoradiographic Study of the Effect of Section of the Facial Nerve on the Uptake of Methionine-^{35}S by the Cells of the Facial Nerve Nucleus

RETROGRADE degeneration of nerve cells was first described by Nissl in 1892[1]. Its main features are swelling of the cells, breaking up of the cytoplasmic chromophile granules and displacement of the nucleus to the cell margin. These changes occur after a lesion in the axon, after excitation of long duration or after certain virus diseases, as, for example, poliomyelitis. It is still not known whether these changes are entirely degenerative in nature or are due to increased metabolic activity associated with increased synthesis of protein molecules. The biochemical processes underlying these changes have so far not been adequately explained. The results obtained from ultra-violet microspectrography of the nucleic acid content of these cells have not been entirely satisfactory[2].

The present communication deals with the results obtained by studying the incorporation of methionine-^{35}S into the affected nerve cells. In a previous investigation[3], it was found that methionine-^{35}S becomes incorporated to a larger extent in the grey matter than in the white matter, and this is in agreement with the findings of other workers[4]. Twenty-four hours after the administration of methionine-^{35}S, 98 per cent of the amino-acid in the brain has become bound to the protein of the central nervous system. The degree of incorporation of methionine-^{35}S therefore indicates the protein synthetic activity of the respective structure.

Five rabbits weighing 3–3·5 kgm. were used for the present investigation. The facial nerve on one side was cut in each animal at a distance of about 3 mm. from the stylo-mastoid foramen. After thirteen days, 500 μc. of methionine-^{35}S was injected intraperitoneally into each animal. All the animals were killed 24 hr. later and the pons and medulla oblongata were removed and fixed in 96 per cent alcohol and then embedded in paraffin wax. The isotope content of all the liquids used in processing the tissues was measured and no activity was found. Histological sections of the facial nerve nucleus area were then prepared so that in one section there were the nuclei of both the injured and the normal facial nerves. The histoautoradiographic 'coating method' was used, the emulsion being prepared as described previously[5]. The duration of exposure was 61 days. The sections were kept in an exsiccator at 4° C. The developed sections were then stained with hæmatoxylin and eosin using the Bélanger method[6].

The degree of blackening of the emulsion coating the section indicated the concentration of the radioactive amino-acid in the section. Photographs of retrograde degenerated cells of the injured seventh nerve nucleus as well as photographs of cells of the normal nucleus were then taken. Photographs were also taken of the emulsion coating at corresponding levels just above these cells. By subtracting the degree of blackening over the surrounding tissues from the amount of blackening over a cell of the seventh nerve nucleus, a value of the incorporation of methionine-^{35}S into the cell of the nucleus was obtained. In addition, the area of each cell was calculated by means of a planimeter. The results were then evaluated statistically.

It was found that more methionine-^{35}S was incorporated into the nerve cells than into the surrounding white matter, thus confirming previous observations. In all the sections the nerve cells of the denervated seventh nerve nucleus had incorporated significantly more methionine-^{35}S than the cells in the normal control nerve nucleus. The planimeter measurements showed that the area of the nerve cells of the denervated nerve nucleus was in most cases greater than the area of the nerve cells of the control nucleus. The nerve cells of the denervated nucleus incorporated per unit area more methionine-^{35}S than the corresponding area of the cells of the control nucleus.

The results therefore show that nerve cells undergoing retrograde degeneration have an increased uptake of methionine, indicating that an increased synthesis of protein molecules is taking place.

Perosis and Folic Acid Antagonism in Chickens

The folic acid antagonist pyrimethamine has been shown to act as a synergist with sulphadimidine against *Eimeria tenella* in chickens[1]. During our investigation of this combination, a decreased growth-rate was noted in chickens fed for five days on an all-mash diet containing 100 p.p.m. of pyrimethamine.

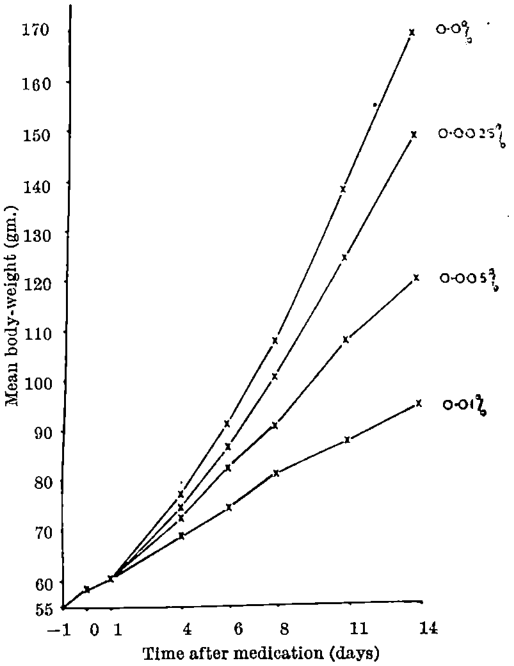
The toxicity of pyrimethamine was therefore examined with four groups of forty chickens which were fed mash containing pyrimethamine 0, 25, 50 or 100 p.p.m. from 7 days of age. The growth-curves are shown in Fig. 1. During the first fourteen days feeding, one chicken fed 25 p.p.m. and two fed 100 p.p.m. died of pyrimethamine poisoning. After fourteen days feeding two chickens were selected at random from each group for hæmatological study. The remainder of each group was randomized by weight into two even sub-groups, one chicken in the group fed 25 p.p.m. being discarded. One sub-group continued on the medicated feed and the other sub-group was fed basal ration. The chickens fed basal ration quickly resumed normal growth. In this period six chickens fed 100 p.p.m. died of pyrimethamine poisoning.

Table 1. Mean Weight Gains, Number of Deaths and Incidence of Perosis in Chickens fed Pyrimethamine 0, 25, 50 or 100 p.p.m. for 14 or 32 Days

Pyrimethamine in diet (p.p.m.) 0–14 days	Pyrimethamine in diet (p.p.m.) 15–32 days	Mean gain in weight (gm.) after 14 days	Mean gain in weight (gm.) after 32 days	Cases of Perosis	Cases of Death
0	0 0	113	393 370	0/19* 0/19	0
25	0 25	93	361 331	2/18 11/18	1
50	0 50	64	307 212	2/19 19/19	0
100	0 100	40	260 101	6/18 13/15†	8

* Number of cases of perosis/number in group.

† Three of these died late in the experiment and were examined for perosis.



Perosis was seen in the medicated groups after twenty-five days feeding. At thirty-two days all chickens were examined for perosis, and Table 1 shows the incidence in the various groups. Some chickens fed 25 p.p.m. pyrimethamine for only fourteen days showed perosis. The diet contained ¼ oz. anhydrous manganese sulphate per 100 lb. mash and was calculated to contain 80 p.p.m. of manganese.

Daniel, Farmer and Norris[2] showed that perosis occurred in chickens fed a diet low in folic acid and was prevented by adding synthetic folic acid to the diet. The addition of succinyl sulphathiazole accentuated the severity of the perosis on a diet low in folic acid. This seems to support the theory that chickens synthesize folic acid from *p*-aminobenzoic acid, which is made by the degradation of folic acid in the diet[3].

In our work, it seems certain that the perosis was due to a deficiency of folic acid caused by pyrimethamine, a potent folic acid antagonist.

A detailed account of these experiments will be published elsewhere.

I am grateful to Burroughs Wellcome and Co. (Australia), Ltd., who generously provided a quantity of pyrimethamine.

A Comparative Biochemical Study of Nucleohistones from Different Vertebrates

RESULTS recently reported by Crampton *et al.*[1] lead those authors to the conclusion that the nucleohistones extracted from the different tissues of the same animal are very similar in composition. Our own investigations on different organs of the calf confirm these results (Table 1, Fig. 1).

Table 1. AMINO-ACID RESIDUE (GM.) PER 100 GM. PROTEIN

	Calf thymus histone	Calf liver histone	Calf kidney histone
Arginine	12·6	11·8	12·3
Lysine	15·5	15·2	16·1
Histidine	2·4	2·5	2·3

Table 2. AMINO-ACID RESIDUE (GM.) PER 100 GM. PROTEIN

	1	2	3	4	5	6	7	8
	Carp erythrocyte histone	Trout erythrocyte histone	Pike erythrocyte histone	Calf thymus histone	Fowl erythrocyte histone	Duck erythrocyte histone	Tench erythrocyte histone	Frog erythrocyte histone
Arginine	13·5	13·5	11·4	12·6	13·3	13·0	—	12·8
Lysine	15·5	15·2	13·5	15·5	16·6	15·7	—	14·0
Histidine	2·3	2·5	1·9	2·4	2·5	2·4	—	2·9

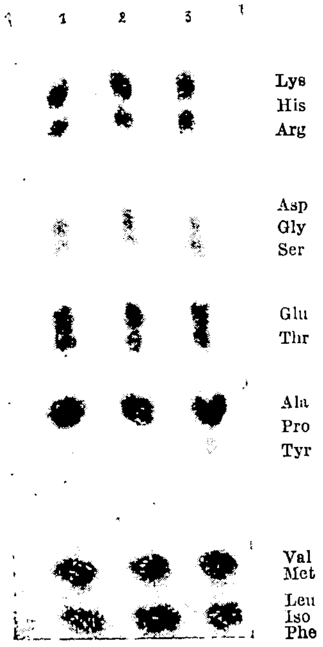

Fig. 1. Chromatograms of nucleohistones extracted in *M* sodium chloride from calf thymus, liver and kidney. Hydrolysates containing identical quantities of deoxyribonucleic acid were used in all three cases. Whatman paper No. 1. Solvent: 4 parts, butanol; 1 part, ethanol; 1 part, acetic acid; 2 parts, water

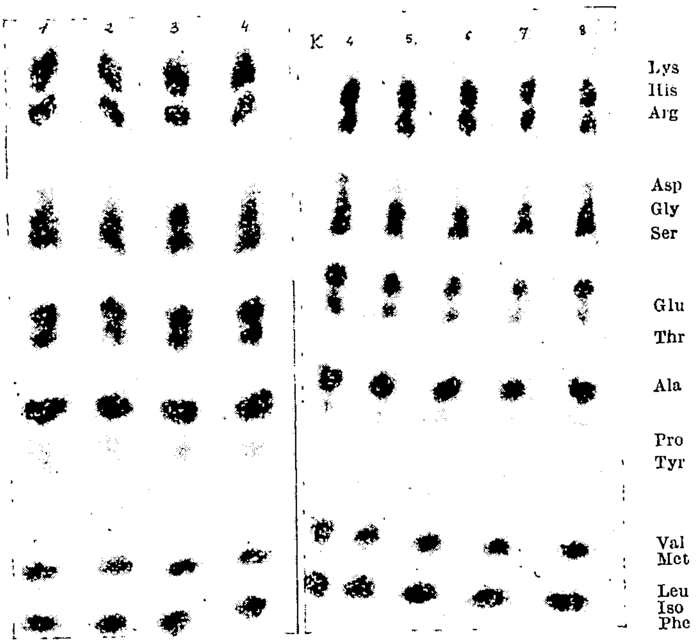

Fig. 2. Chromatograms of nucleohistones from different vertebrates (each volume of hydrolysate corresponds to the same quantity of deoxyribonucleic acid. Nucleohistone from: (1) carp erythrocytes; (2) trout erythrocytes; (3) pike erythrocytes; (4) calf thymus; (5) fowl erythrocytes; (6) duck erythrocytes; (7) tench erythrocytes; (8) frog erythrocytes. Whatman paper No. 1. Solvent: 4 parts, butanol; 1 part, ethanol; 1 part, acetic acid; 2 parts, water

But a comparison of nucleohistones extracted from different animal species is also of interest. For that reason, we have studied nucleoproteins isolated by the technique of Signer and Schwander[2] from different materials, namely, calf thymus and erythrocytes of carp, trout, pike, tench, frog, fowl and duck. Chromatograms were made of all these nucleohistones. Before chromatography, the hydrolysates were adjusted to identical content of deoxyribonucleic acid, in order to permit an easy comparison of the chromatograms run in parallel on the same paper (Fig. 2). The amounts of arginine, lysine and histidine in all these nucleohistones were also determined (Table 2).

This comparison reveals a striking similarity between all the nucleohistones studied, so it appears that if differences do exist between the histones of the various animals, they are beyond the sensitivity of our analytical technique. The classical results of Chargaff[3], at least concerning vertebrates, on the analysis of deoxyribonucleic acid from different organs of an animal and the same organ in various animal species (mammals, birds, fishes and reptiles) fail to reveal very marked differences between these deoxyribonucleic acids, though the slight differences detected could be significant. In the nucleohistone a similarity of general composition seems to occur in the samples studied, and reflects the similarity of the general composition of the nucleic acids.

Rate of Body-Water Distribution studied with Triple Labelled Water

The rate of equilibration of extra- and intracellular water is determined by the passage of the water through the cell membrane. The transfer of water through cell membranes can proceed by various mechanisms. The simplest mechanism is diffusion of water molecules as a whole. Another mechanism is a biological carrier system, such as exists, for example, in the tubular mechanism of the kidney; and another route of transfer is ionic migration of protons and hydroxyl ions independently through the cell membrane.

In order to elucidate the mechanism, water triply labelled with oxygen-18, deuterium and tritium was used. The aqueous system injected into rabbits contained therefore primarily H^{16}OH, H^{16}OD, H^{18}OH and H^{18}OD in equilibrium. The experiments, which were carried out on rabbits, were aimed at comparing the rates of transfer of the three isotopes from the blood to the intracellular volume and at the determination of the total volume of their distribution.

In our experiments, water containing 16–20 per cent of oxygen-18, 35–45 per cent of deuterium and 5–50 μc. of tritium per ml. was injected into the rabbits intravenously. Blood samples were withdrawn at intervals, centrifuged and the water distilled on a vacuum line at room temperature. The isotopic composition of oxygen was determined by decomposition of the water by alkaline hypobromite solution over cobaltic oxide in a sealed ampoule[1], the oxygen gas being analysed on a *CEC*21–401 isotope-ratio mass spectrometer. Two other portions of the water were totally reduced to hydrogen by zinc powder in sealed ampoules at 400° C., and one of these was analysed by a hydrogen/deuterium isotope-ratio mass spectrometer; the other hydrogen sample was introduced into a Geiger counter for activity determination. Some typical results are shown in Table 1.

Table 1. Volume of Distribution of Labelled Water in Rabbits

Rabbit No.	Time after injection (min.)	Isotopic composition of blood samples: Oxygen-18 (per cent)	Deuterium (per cent)	Tritium (μc.)	Volume of distribution from isotope dilution*: Oxygen-18 (ml.)	Deuterium (ml.)	Tritium (ml.)
*U*2	2·5	0·267	0·168	2·5 × 10^{-2}	1,260	1,235	1,278
*U*2	10	0·260	0·151	2·25 × 10^{-2}	1,415	1,392	1,420
*U*2	29	0·254	0·140	2·07 × 10^{-2}	1,560	1,517	1,542
*U*2	140	0·250	0·129	1·98 × 10^{-2}	1,670	1,665	1,615
A–3	4	0·274	0·235	1·40 × 10^{-1}	1,320	1,295	1,250
A–3	40	0·262	0·210	1·15 × 10^{-1}	1,570	1,545	1,525

* *U*2 was injected with 5 ml. of water containing: oxygen-18, 18·6 per cent; deuterium, 37·6 per cent; and tritium, 6·4 μc./ml. The isotopic composition of the blood was found to be before injection: oxygen-18, 0·195 per cent; deuterium, 0·016 per cent; tritium, zero activity. *A*–3 was injected with 5 ml. of water containing: oxygen-18, 18·4 per cent; deuterium, 40·3 per cent; and tritium, 33·3 μc./ml. This rabbit had been used in previous experiments so that its body water (blood) was slightly isotopically enriched at the time of injection, namely oxygen-18, 0·20 per cent; deuterium, 0·08 per cent; tritium, 5·4 × 10^{-3} μc./ml.

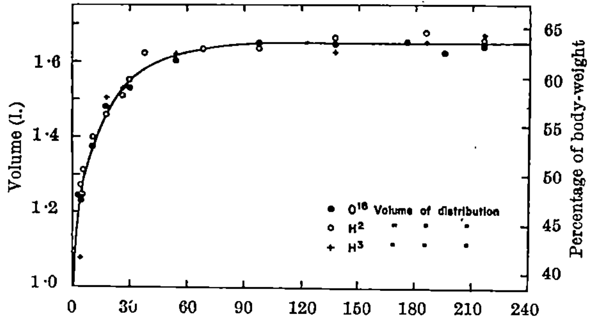

Fig. 1. The rate of distribution of water labelled with oxygen-18, deuterium and tritium as a function of time

Our results show that, within the experimental accuracy, no difference could be found in the rates of distribution of the three isotopes and their respective volumes of distribution (Fig. 1). (The standard deviations for the determination of oxygen-18, deuterium and tritium were 1, 2 and 2 per cent respectively.) The percentage of body water in our measurements is in full agreement with values obtained with deuterium as a tracer[2]. The small differences in fluid volumes of distribution could be explained either by the different rates of exchange between these isotopes and body constituents on one hand and the different routes of excretion on the other. Different results were obtained, however, in deeply anæsthetized animals.

The biological half-lives for oxygen-18, deuterium and tritium in rabbits were found to be 80, 220 and 130 hr. respectively (with a standard deviation of 10 per cent). The shorter biological half-life of oxygen-18 may be due to the additional route of excretion by expiration. The difference between tritium and deuterium may indicate a proton-transfer mechanism in the excretion process in which an isotope effect is involved.

As no appreciable difference could be detected between the rates of distribution of the three isotopes, it may be concluded that under normal conditions the most probable mechanism for water transfer through the cell membrane involves water molecules as such, and does not involve the breaking of the hydrogen–oxygen bond or prior ionization.

Radioprotective Properties of Cystamine, Cysteamine and Cysteine when tested with Chick Fibroblasts *in vitro*

It is well known that a number of SH-containing compounds afford a certain amount of radioprotection to many organisms[1,2]. However, little information is available about the effects on cells *in vitro*. The present report deals with a series of experiments on the effects of cystamine, cysteamine and cysteine when added to cultures of chick fibroblasts shortly before irradiation.

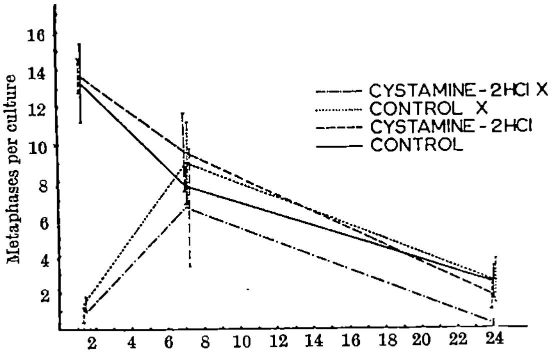

Fig. 1. Number of metaphases in hanging-drop cultures after treatment with 0·44 m*M* cystamine–2 hydrochloride and 200r. X-rays. The number of cultures for each point is 12 in the non-irradiated controls and 6 in the other groups

Heart fibroblasts from 9-day-old chick embryos were cultivated in standard media either in hanging drops or in Carrel flasks. The test substances were added in Tyrode solution, and the cultures were irradiated 15 min. later with 175 kV. X-rays, 0·5 mm. copper filtration, tissue dose-rate 50–100 r./min., under conditions of maximum back-scatter, in a water or air thermostat.

Mitotic inhibition was investigated in hanging-drop cultures. After 48 hr. in the second passage after explantation a non-toxic solution of 0·11 m*M* or 0·44 m*M* cystamine–2 hydrochloride or 0·21 m*M* cysteine–hydrochloride was added before irradiation with 200r. Prophases, metaphases, anaphases and telophases were counted in stained cultures, fixed 80 min. 4 hr., 7 hr. or 24 hr. after irradiation. The results obtained show that the radiation-induced mitotic inhibition was not influenced by the addition of either cystamine or cysteine in the above concentrations. Fig. 1 shows a typical response pattern.

Growth inhibition was investigated in cultures which were grown in Carrel flasks. When the explants had been cultured for four days, the liquid phase was substituted with test solution or Tyrode, and the cultures were irradiated. After irradiation the cultures were washed, and new liquid phase was added. Three days after treatment, the cultures were transferred to hanging drops and grown for 10–15 passages. At the end of every passage, each culture was scored as living or dead, the area of the growth migration zone was measured, and throughout the experiment the same person evaluated the vigour of each culture. Several concentrations of cystamine–2 hydrochloride, cysteamine–hydrochloride and cysteine–hydrochloride were tested after 1,500, 2,000 and 3,000r. After irradiation with such doses, the cultures deteriorate rapidly during the first 4–6 passages, after which most die in the next 5–10 passages.

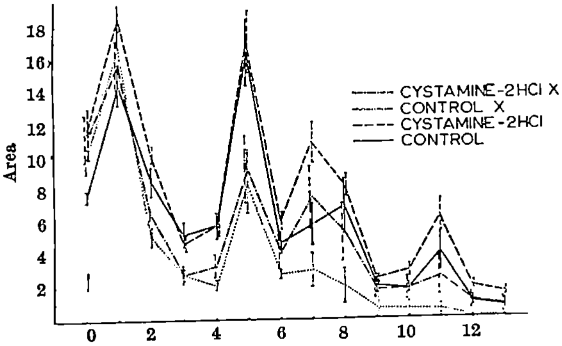

Fig. 2. Change with time of average area for 12 cultures irradiated with 1,500r. after addition of 0·89 m*M* cystamine–2 hydrochloride and controls, with standard deviation of the mean. × = irradiated groups

The results obtained show that the addition of 0·89 m*M* cystamine–2 hydrochloride before irradiation with 1,500 or 2,000r. helps the cultures through the critical phase which seems to occur after 4–6 passages. After this point the 'protected' cultures do better than the controls, having more survivors, a larger growth zone, and giving a more healthy impression. Fig. 2 shows average growth-zone areas from a typical experiment. It will be noted that the two groups of irradiated cultures have about the same area in the first 6 passages, but that during the subsequent passages the cultures receiving cystamine approach the non-irradiated controls. There is also a certain difference to be seen between the two groups of non-irradiated cultures. For cysteamine–hydrochloride or cysteine–hydrochloride no similar protective effect could be found.

The observed effect of cystamine may be explained as a result of one or more mechanisms operating during and immediately after irradiation[3,4]. However, the effect may also be attributed to a general growth-promoting property of cystamine in the concentration used. A combination of these two explanations is also possible.

A complete report will be published in the twenty-fifth anniversary publication of the Norwegian Radium Hospital.

The technical assistance of Miss Brit Falck Madsen and Miss Gudrun Braarvig is gratefully acknowledged. The investigation has been supported by the Norwegian Cancer Society.

Immediate Effect of *l*-3 : 5 : 3′-Tri-iodothyroacetic Acid on Metabolic Rate and Body Temperature in Hypophysectomized Rats and the Action of Cortisone

The acetic acid analogues of thyroxine and tri-iodothyronine have been found to raise the metabolic rate of the thyroidectomized[1–4] and the hypophysectomized[3,4] rat without latency. In hypophysectomized rats intravenous injection of a few micrograms of tri-iodothyroacetic acid is invariably followed by a marked rise in oxygen consumption and body temperature, while only about half the thyroidectomized and none of the intact rats show a similar response[4].

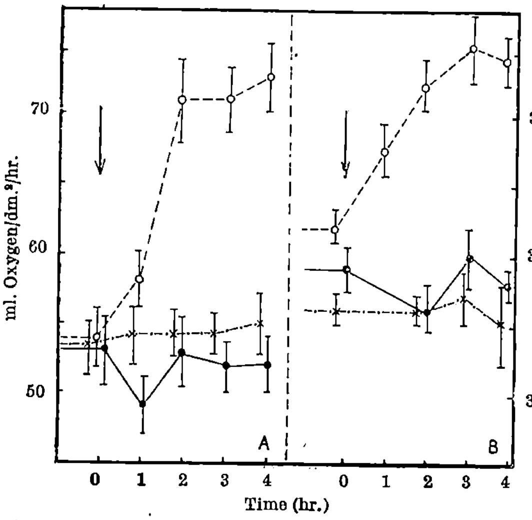

Fig. 1. Effect of 5 μgm. tri-iodothyroacetic acid injected intravenously on oxygen consumption (*A*) and body temperature (*B*) in the hypophysectomized rat ($n = 23$), O — — — O; in the cortisone-treated hypophysectomized rat ($n = 10$), ×—.—.—×. Effect of 0·2 ml. solvent on oxygen consumption (*A*) and body temperature (*B*) of the hypophysectomized rat ($n = 10$), ●——●

Experiments performed a few weeks after removal of the pituitary in adult male rats, and summarized in Fig. 1, demonstrate the marked rise in oxygen consumption and body temperature following intravenous injection of 5 μgm. of tri-iodothyroacetic acid (Glaxo), and show that both effects are completely abolished by 1 mgm. of cortisone (Organon) administered three hours earlier. (In some experiments a single cortisone injection was given, in others the rats received 1 mgm. daily for 2–3 days, the last being administered three hours before injecting tri-iodothyroacetic acid.) Injection of the solvent had no effect, nor did cortisone abolish the effect of a highly purified pyrogen[5], so that contamination with pyrogen can be excluded.

A large number of old and new observations tend to show an interaction of the thyroid and the adrenal gland[6], but, with the exception of adrenal hypertrophy in hyperthyroidism and atrophy in hypothyroidism and their experimental counterparts, the results are not very conclusive, and mainly concern the action of corticosteroids on the secretion of thyroid-stimulating hormone. The present experiments seem to be the first to demonstrate that a corticosteroid interferes with the action of a iodothyronine derivative.

That lack of adrenal cortical function is an essential condition for the manifestation of an immediate effect of tri-iodothyroacetic acid on oxygen consumption and body temperature is supported by the following observations. (1) No immediate response can be obtained in the hypophysectomized rat adequately treated with adrenocorticotrophic hormone. (2) An immediate response was elicited in all adrenalectomized rats, which later, after the withdrawal of sodium chloride, died of adrenal insufficiency. (3) The immediate response can be observed sixteen hours after the removal of the pituitary. (4) The immediate response in the hypophysectomized rat is not abolished by elevating the reduced metabolic rate to a normal or even high level by the administration of thyroxine.

Adrenal hypofunction may possibly be an adequate explanation for the less regular incidence of the immediate response in the thyroidectomized rat.

Immediate effects similar to those with tri-iodothyroacetic acid were obtained also with 3 : 5 : 3′-tri-iodothyronine (Glaxo) and some brands of thyroxine. Interpretation of these results is difficult, for as paper chromatographic analysis shows, iodothyronine preparations often contain more than a single compound[3,7].

We wish to express our thanks to Glaxo, Ltd., for the sample of tri-iodothyroacetic acid (Triac), to Organon N.V. for the cortisone and to Dr. O. Lüderitz (Säckingen) for the purified coli pyrogen.

Distribution of Carbon-14 in Components of Goat's Milk, with Sodium Formate-^{14}C as Precursor

In a report dealing with the biosynthesis of milk components by the cow, Kleiber[1] described the use of sodium formate labelled with carbon-14 as one of the precursors. This communication reports the transfer of carbon-14 to the components of goat's milk when formate was the precursor.

A grade goat was injected intravenously with 30 mc. of sodium formate-^{14}C (Tracerlab) dissolved in 10 ml. of saline (0·85 per cent). Prior to dosing the animal, residual milk was removed from the

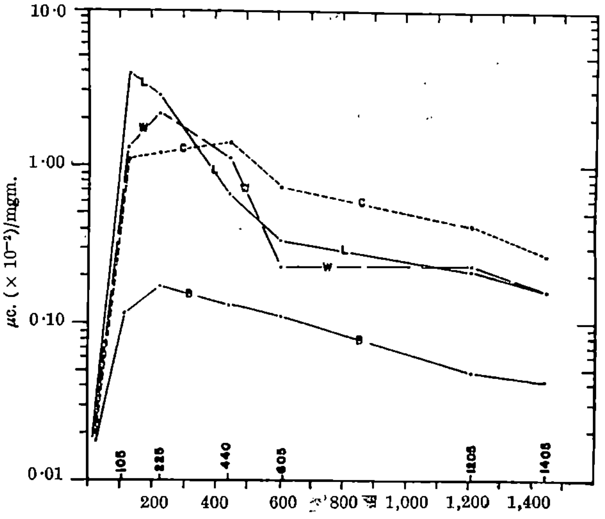

Fig. 1. Specific activity of milk components : ·—*B*—● , butterfat activity ; -----*C*---- , casein activity ; ·—*L*—● , lactose activity ; ·—*W*—· , whey–protein activity

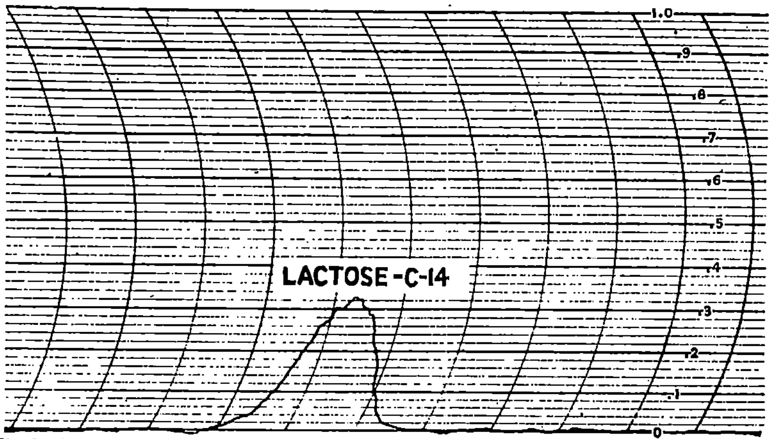

Fig. 2. A scanning record of a chromatogram containing 600 µgm. ($58 \cdot 6 \times 10^{-4}$µc.) of a sample of lactose-^{14}C

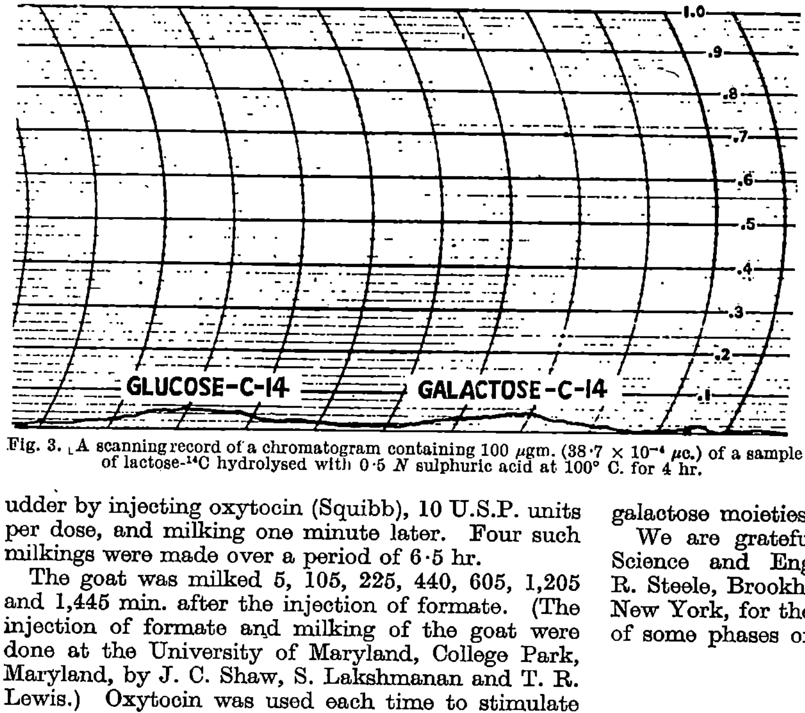

Fig. 3. A scanning record of a chromatogram containing 100 µgm. ($38 \cdot 7 \times 10^{-4}$ µc.) of a sample of lactose-^{14}C hydrolysed with 0·5 *N* sulphuric acid at 100° C. for 4 hr.

udder by injecting oxytocin (Squibb), 10 U.S.P. units per dose, and milking one minute later. Four such milkings were made over a period of 6·5 hr.

The goat was milked 5, 105, 225, 440, 605, 1,205 and 1,445 min. after the injection of formate. (The injection of formate and milking of the goat were done at the University of Maryland, College Park, Maryland, by J. C. Shaw, S. Lakshmanan and T. R. Lewis.) Oxytocin was used each time to stimulate the flow of milk. Each batch of milk was immediately frozen in 'dry ice', and held in the frozen state until it was fractionated.

After thawing the milk at 40° C., butterfat was separated by centrifugation and casein was precipitated at the isoelectric point. Precipitable whey-protein was separated by adjusting the *p*H of the whey to 4·0 with dilute hydrochloric acid. To facilitate the flocculation of the serum proteins, sodium bisulphite was added on a 0·1 per cent w/v ratio, based on the original volume of milk from which the whey was obtained[2]. The whey was heated at 95° C. for ten minutes and cooled to 20–30° C. before removal of the precipitate.

Since pure lactose-^{14}C was needed for metabolism studies, impurities were removed from the lactose in the following manner: 'Norit *A*' (Pfanstiehl) was added to the crude lactose at a level of 3 per cent of the original whole-milk volume. The mixture was heated to 95° C., centrifuged for 5 min. at 2,000 r.p.m. and decanted on to Whatman No. 5 filter paper. The filtrate was concentrated by evaporation on a steam-bath and was then freeze-dried. The lactose was dissolved in small quantities of boiling water, and the temperature was lowered gradually to −5° C. Methanol (two volumes) was added to reduce the solubility of the lactose, permitting crystallization at −5° C. in 48 hr. The crystals of lactose were then washed with methanol and dried with ether.

All samples for assay were combusted by the method of Gabourel[3], and carbon-14 was counted as $Ba^{14}CO_3$. As shown in Fig. 1, the specific activity of the lactose reached a maximum value 105 min. after the injection of the precursor, whey-protein and butterfat at 225 min., and casein at 440 min.

A sample from each batch of lactose was paper-chromatographed and scanned[4] for the detection of radioactive impurities. Samples showing radioactive contamination were recrystallized until the interfering activity was eliminated (Fig. 2). A sample of the purified lactose was hydrolysed with 0·5 *N* sulphuric acid in a sealed tube for 4 hr. at 100° C. The hydrolysate was adjusted to *p*H 4·5 with a saturated solution of barium hydroxide, filtered, condensed, chromatographed and scanned. The scan showed that the activity was equally distributed between the glucose and galactose moieties (Fig. 3).

We are grateful to Drs. A. Edelmann, Nuclear Science and Engineering Corp., Pittsburgh, and R. Steele, Brookhaven National Laboratory, Upton, New York, for their suggestions during the planning of some phases of this experiment.

Occurrence of Rhodanese in a Species of *Thiobacillus*

THE enzyme rhodanese which catalyses the reaction:

$$S_2O_3'' + CN' \rightarrow CNS' + SO_3$$

has been shown to be present in *Thiobacillus thiocyanoxidans*. Cells of the organism, grown in thiosulphate medium with forced aeration and 2–5 per cent of carbon dioxide added[1], were harvested in a de Laval centrifugal separator, washed and suspended in $M/15$ phosphate buffer, pH 7·0.

Rhodanese activity was tested by the following procedure. Duplicate, 12-in. test-tubes containing: 0·5 ml., 0·125 M sodium thiosulphate; 0·5 ml., 0·125 M potassium cyanide; 0·5 ml., 0·2 M potassium dihydrogen phosphate; 1·0 ml. cell suspension (washed) were incubated at 30° C. for 15 min., the final pH of the mixture being 8·3. After incubation, the reaction was stopped by the addition of 0·5 ml. of 36 per cent formaldehyde. A blank tube was included in which the formaldehyde was added at the outset of the incubation period. The contents of the test-tubes were diluted with 25 ml. distilled water and centrifuged on a bench centrifuge to remove bacterial cells. 2·5 ml. ferric nitrate reagent were added to the clear supernatant, and the colours obtained were read at 470 mμ in a Unicam *S.P.* 600 spectrophotometer.

The following results were obtained:

Tube	Optical density at 470 mμ
Blank	0·01
I	0·750
II	0·735

These results seemed to indicate the presence of rhodanese. Boiled cells of *Th. thiocyanoxidans* were also incubated with thiosulphate, cyanide and potassium dihydrogen phosphate at pH 8·3, but there was no production of thiocyanate.

Another possibility was that thiocyanate might be formed from the chemical combination of cyanide and tetrathionate, the latter compound being a probable intermediate in thiosulphate oxidation by *Thiobacilli*.

To preclude this possibility the test for rhodanese was carried out under anaerobic conditions, in Thunberg tubes, which had been evacuated and filled with nitrogen. The results of this experiment indicated that the formation of thiocyanate from thiosulphate and cyanide does not involve the oxidation of thiosulphate to tetrathionate, but is a straightforward trans-sulphuration as required by the rhodanese reaction.

The production of thiocyanate with time is shown in Table 1.

Table 1. Thiocyanate Production when Washed Cells of *Th. thiocyanoxidans* are Incubated with Cyanide and Thiosulphate

Time (min.)	Thiocyanate (μgm./ml.)
10	55
30	65
40	70
60	76
80	81
120	85

The effect of varying the concentration of cyanide was tested. Reaction tubes were set up containing a standard amount, namely, 0·5 ml. of 0·05 M thiosulphate; the cyanide concentration was varied, as was the potassium dihydrogen phosphate concentration, so that the optimum pH of 8·3 was maintained.

Tubes were incubated at 30° C. for 70 min. and the reaction stopped by the addition of 0·5 ml. of 36 per cent formaldehyde. The tubes were centrifuged and their contents assayed with ferric nitrate for thiocyanate. The results are given in Table 2.

Table 2. Effect of Varying the Cyanide Concentration on the Production of Thiocyanate by *Th. thiocyanoxidans* from Thiosulphate and Cyanide

Molarity of potassium cyanide	Thiocyanate formed (μgm./ml./70 min.)
0·25	55
0·125	35
0·0025	20
0·005	5

If the concentration of thiosulphate is taken as the limiting factor for the production of thiocyanate, these results show that the rhodanese system is not inhibited by an excess of cyanide. This is a significant point of difference between the pure crystalline rhodanese obtained by other workers[2] and the rhodanese present in *Th. thiocyanoxidans*.

These latter results must, however, be treated with caution as they involve a comparison between a pure crystalline enzyme and whole cells.

This work was carried out with the encouragement and under the supervision of Prof. F. C. Happold and was aided by a grant from the Gas Research Council.

Localization of Oxidative Enzyme Systems in the Uterus and Vagina of the Rat

The evolution of histochemical methods for the localization of oxidative enzyme systems in tissues[1] has made it possible to study the effects of endogenous hormones on the intensity and distribution of such enzymes in reproductive organs. Enzyme systems concerned with succinate and lactate oxidation in the uterus and vagina of the rat have been previously shown to be markedly under the influence of changes in the normal endogenous hormonal balance in the female albino rat[2]. We have now followed the histochemical changes in the uterus and vagina of the rat through the œstrous cycle.

Albino rats, 100 days old, were studied by the vaginal smear technique through three consecutive œstrous cycles. During the fourth cycle, regularly cycling females were selected for study at the following stages: preproœstrus, proœstrus, œstrus, metœstrus, 36-hr. diœstrus and 60-hr. diœstrus. The animals were killed by concussion and pieces of vagina and uterus were frozen immediately on 'dry ice', sectioned at 30μ and stained for succinate oxidation according to a procedure previously outlined (ref. 1, *b*). Staining as a result of lactate oxidation was carried out in a similar fashion with 4·0 ml. of 1·0 M sodium lactate substituted for succinate, 26 ml. of phosphate buffer with cyanide, and an addition of 4·0 ml. of lactate oxidation (1·0 mgm./ml.) in buffer. All tissues were studied by photographing the stained preparations under standardized conditions and comparing prints for intensity of staining.

Examination of vaginas at various stages of the œstrous cycle for lactate oxidation diaphorase showed that the most intense activity was displayed at periods characteristic of high œstrogen titre in the animal (preproœstrus, proœstrus and œstrus); while during metœstrus and both stages of diœstrus vaginas displayed considerably lower degrees of enzymatic oxidation. In the former more active stages, the localizations of lactate oxidation were concentrated in areas of the vaginal epithelium known to be metabolically active at this time. The germinative and luminal layers of epithelium during preproœstrus and proœstrus showed an intense reaction (Fig. 1,1). The cells of the lumen have been previously identified with high mucin production[3].

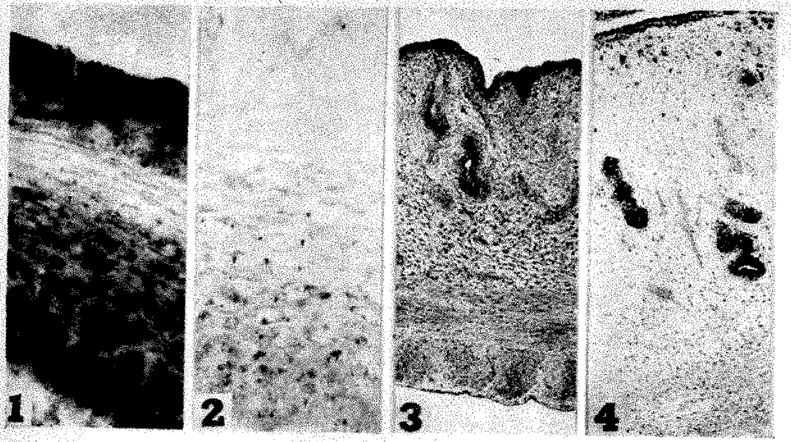

Fig. 1. 1, Lactate oxidation diaphorase in vaginal epithelium at prooestrus. Note high activity in luminal (upper) and germinative (lower) layers. Cornified cells (middle) show no activity. 2, Vaginal succinate oxidation activity at preprocestrus. Mucin-producing cells (upper) are inactive, whereas the germinative layer shows little staining. Cells undergoing cornification (middle) are losing much of the enzyme. 3, Procestrus uterus containing high lactate oxidation activity in the luminal and glandular epithelium. Considerable staining also occurs in the stromal and muscular elements. 4, Late procestrus or early œstrus uterus showing high succinate oxidation activity in epithelium and a low to negative reaction in the stroma. Muscle is lightly stained (lower right)

Consistent with current beliefs concerning the lowered metabolism or inactive state of cornified cells, our results demonstrated little or no enzymatic activity within such structures.

Oxidative enzymatic activity as a result of the succinate oxidation demonstrable with these methods was quite low in intensity. Although the highest activity was shown during œstrus and procœstrus, vaginas stained at these times had low activity in the germinative layers and no perceptible activity in cornified and mucified cells (Fig. 1,2). It should be noted that the apparent absence of succinate oxidation activity in cells producing mucin represents a feature quite distinct from that of lactate oxidation activity in similar cells. Mucin production as a result of exogenous œstradiol stimulation of the vagina has been shown to be associated with lactate oxidation diaphorase[4].

Uterine succinate oxidation and lactate oxidation was maximal during procœstrus when large quantities of fluid are found within the lumen of the uterus. Lactate oxidation activity was localized within the luminal and glandular epithelium, stromal cells and myometrium (Fig. 1,3). The greatest activity was associated with epithelial structures and this is probably a reflexion of increased oxidative metabolism of these structures requisite for synthetic and secretory activity[5]. Stromal connective tissue cells showed moderate to high staining within the cytoplasm, while the nuclear constituents were apparently unreactive. Muscle stained moderately throughout. The high activity of epithelial structures decreased considerably during metœstrus and continued to drop even further at diœstrus. Generally, both stromal elements and muscle showed a considerable reduction in enzymatic activity at these stages.

Succinate oxidation appeared to be very low or absent from the uterine stromal cells throughout all stages of the œstrous cycle. A drop in succinate oxidation activity was evident at late procœstrus or early œstrus, and was most pronounced in the myometrium, with a lesser loss evident in the epithelium (Fig. 1,4). With the onset of diœstrus and throughout this stage, both muscle and epithelium contained a low level of succinate oxidation.

It is believed that the above changes in succinate and lactate oxidation offer further evidence that these enzyme systems are under the influence of the changing hormonal environment within the animal. In addition, these results suggest that different structures or tissues within the same organ respond individualistically to presumably the same hormonal balance, thereby indicating that adequate histochemical localization of a given enzyme should be included with quantitative data such as that derived from homogenate studies. Enzyme distribution in the vaginal epithelium indicates clearly the type of error that can be introduced in homogenate studies if the mass of the tissue is not also considered in terms of highly active areas of oxidation coexistent with totally inactive (keratinized) regions within the same organ (Fig. 1, 1 and 2).

Variation with Age of Shrinkage Temperature of Human Collagen

During the course of an investigation of hydrothermal shrinkage temperatures of human tissue, we examined many samples of different ages. Small fibres were teased out from the tissue immersed in 0·9 per cent sodium chloride solution and transferred with salt solution to a capillary tube. This was placed in a micro-melting point apparatus (Gallenkamp) and the shrinkage temperature determined by viewing under low magnification. The voltage across the heating element was controlled by a rheostat to give a rise of not more than 2 deg. per min. The temperatures at which the fibres started and finished shrinking were designated Ts_1 and Ts_2 respectively. Samples were taken from dura mater or fascia lata at autopsy or at operation from cases not suffering from 'connective tissue' disease and were examined without delay. In saline, fibres from either tissue from any one individual shrunk over the same range, and there was no difference between different fibres from one tissue. Results are given in Table 1.

Statistical analysis shows that for Ts_1 the variation ratio (F) between the groups is 35·3, which is highly

Table 1. Variation of Shrink Temperature with Age

Age group	Ts_1 (° C.)		Ts_2 (° C.)		No. of cases
	Mean	Range	Mean	Range	
Fœtuses 12–40 weeks	54·4	53–55	60	59–62	7
0–14 years	57·7	55–59	63·9	61–67	12
15–25	59·8	57–62	65·7	64–68	7
26–44	59·1	57–61	66·2	65–67	8
45–88	61·2	59–63	67	66–68	18

significant. The standard error for Ts_1 (single determination) is 1·33 and the least significant difference between the groups is 1·43 ($P = 0·05$) for means of seven determinations in each group and correspondingly less where the number in a group is greater than seven. It is seen that, except between the age-groups 15–25 and 26–44 years, the difference of the means between groups is greater than 1·43, and we therefore conclude that in any two age-groups, with the exception of those mentioned above, the Ts_1 is significantly higher in the older group. The Ts_2 figures clearly follow the same pattern and the same conclusions apply here.

A similar investigation was carried out with collagen fibres of human uteri and the results are given in Table 2. Here the tissues are divided into only two groups, 45 years being chosen as the approximate age of menopause. Except for one case aged 4 months, the younger group ranged from 25 to 45 years of age and four of these were pregnant; the range of the older group was 49–78 years. Within each group there appeared to be little variation of Ts_1, and statistical analyses showed that the Ts_1 means differed in a highly significant way between the two groups ($F = 14·41$; standard error of $Ts_1 = 1·74$; least significant difference of the means between the groups $= 1·37$ for $P = 0·05$). Ts_2 did not vary significantly between the two groups. By comparison with results in Table 1, collagen from the uterus up to about the age of menopause is seen to be closely similar, as regards hydrothermal stability, to fœtal collagen. Uterine collagen in the older group, on the other hand, resembled the 0–14 year collagen.

Table 2. Shrink Temperature of Human Uteri

Age (years)	Ts_1 (° C.)		Ts_2 (° C.)		No. of cases
	Mean	Range	Mean	Range	
Under 45	55·2	53–57	63·4	61–67	12
Over 45	57·8	55–61	63·1	61–67	16

Few studies of shrinkage temperature and age have been carried out on human tissue; but recently Hall and Reed[1] found that, in water, there was no difference with age in a group of twelve people whose ages ranged from 7 to 89 years. With one exception the range of shrinkage was 62–69·5°, which is somewhat higher than our range of 55–68° covering similar ages. This confirms our observation that shrinkage temperatures are higher in water than in saline, and it might be that, in water, any shrink temperature variation with age would not be evident.

The results reported here add further to the evidence, already accumulated from investigations of other properties[2–6], which demonstrate that collagen becomes more stable with age in the organism. Fœtal collagen is of special interest. Its consistently low shrinkage temperature, whatever the stage of development, suggests that there is a certain minimum degree of stability of collagen once it is laid down as a fibre, and that there is little change in this stability during fœtal life. It would appear from our results that, with growth and development, the collagen becomes further stabilized from birth until adolescence. There is no further stabilization until after middle age, when the subsequent shrinkage temperature rise may be a manifestation of the ageing process.

Harkness and Harkness[7] have shown that the uterus is exceptional in its property of rapid formation and rapid absorption of collagen during and after pregnancy, and in this property of more rapid metabolism it resembles collagen in young growing tissue[6]. The low shrinkage temperatures of uterine collagen would also suggest that it is a less mature form than collagen from elsewhere in the adult, though it is somewhat more stable after the menopause.

This work forms part of an investigation of the shrinkage temperatures of normal and abnormal human collagen, which it is intended to publish in full shortly.

We thank Miss B. M. Haines for introducing us to the micromethod of measuring shrinkage temperatures.

One of us (P. B.) is in receipt of a grant from the Medical Research Council.

Role of Phage Antibodies in the Development of Non-toxigenic Cultures of *Corynebacterium diphtheriae*

That the toxigenicity of diphtheria cultures is associated with the lysogenic state is well established. It now seems that the loss of ability to produce toxin may be mediated by the action of antiphage serum upon lysogenic cultures.

In guinea pigs given intracutaneous injections of virulent cultures of *C. diphtheriae*, and protected against death by the intraperitoneal administration of antitoxin some hours later, a low-grade infection may persist for several weeks. During the latter part of this period non-toxigenic, non-lysogenic cultures may be isolated from the lesions. At this time, also, the presence of phage-neutralizing antibodies in the animals' blood can be demonstrated.

Moreover, if antiphage serum is produced in rabbits by injection of filtered lysates of toxigenic diphtheria cultures, and a toxigenic culture is grown in broth fortified with this, after some ninety daily passages in the presence of these antibodies the culture is found to have become non-lysogenic and avirulent.

The avirulent cultures obtained either by the *in vivo* or the *in vitro* methods regain their virulence upon lysogenization with phage.

of Science PHYSICS Dept. Circular Rd, Calcutta

It is well known that in other lysogenic species there is concomitantly (*a*) spontaneous induction of some cells resulting in subsequent lysis and liberation of phage, and (*b*) more or less frequent failure in transmission of prophage during cell division, so that non-lysogenic cells arise. Normally the latter are either lysed or lysogenized by the infectious phage present in the environment, so that a state of equilibrium is reached. It is known, also, that the addition of citrate or oxalate to the culture medium can prevent re-infection, and that by this method, after many transfers, cultures free of phage can be obtained. The findings outlined above suggest that antibodies to phage, by binding free virus, may bring about the same result.

It should be recalled that Jungeblut[1] found thirty years ago that six passages of virulent cultures in broth containing antitoxin brought about a loss of ability to produce toxin ; but his evidence suggested that this was a transient phenomenon. Some of our converted cultures have remained non-toxigenic during ten passages over a six-month period.

The work reported here offers support for the hypothesis that antiphage bodies are important in conversion, and may account for the occurrence of the avirulent cultures isolated from throats and from the lesions of the chronic cutaneous diphtheria cases found in some parts of the world.

Protein Degradation of Fœtal and Cancer Tissues in the Presence of Ethionine

INTRACELLULAR proteolytic enzymes are present in many tissues and they hydrolyse proteins during autolysis. Some experimental data support the idea of a physiological action of these enzymes : the augmentation of catheptic activity during the regression of cancer[1], and of larval tails of *Xenopus*[2]. But it has been shown that intracellular protein degradation is dependent on energy[3], and that *o*-fluorophenylalanine, a well-known anti-amino-acid, inhibits protein catabolism[4,5]. Steinberg *et al.*[5] also showed that this compound does not influence catheptic proteolysis. These observations lead to the supposition of a mechanism of protein degradation different from that of the simple catheptic hydrolysis. Similar conclusions are reported by Yakovlev[6], who studied the action of phosphate, dinitrophenol and other substances on proteolysis of tissues. He reported also that fœtal tissues behave against dinitrophenol differently from the normal rat tissues.

I have investigated the action of another anti-amino-acid, ethionine, upon the intracellular protein degradation of normal and fœtal liver and of benzopyrene sarcoma. In all cases 400-mgm. aliquots of 0·5-mm. tissue slices are incubated for 3 hr. at 37° in 4 ml. phosphate buffer $M/15$ at *p*H 7·2 containing ethionine 2×10^{-3} M. At zero time, and at the end of the incubation, the slices are homogenized in their medium and proteins are precipitated with an equal amount of 14 per cent trichloracetic acid. On the supernatant the ninhydrin-positive substances are determined colorimetrically[7]. Table 1 gives the values of the amino-acids released in control experiments and those carried in the presence of ethionine.

Table 1. INHIBITION OF PROTEIN BREAKDOWN IN NORMAL AND FŒTAL RAT LIVER AND OF BENZOPYRENE SARCOMA

	mgm. released amino-acids/100 gm. fresh weight		
	Controls		Ethionine
	Zero time	3 hr.	3 hr.
Normal liver	108 ± 11	210 ± 18	117 ± 13
Fœtal liver	122 ± 13	180 ± 17	130 ± 13
Sarcoma	150 ± 14	270 ± 22	244 ± 21

The control experiments show decreased degradation of fœtal proteins, and increased degradation in sarcoma. In the presence of ethionine, degradation in sarcoma is slightly inhibited by the anti-amino-acid (only 20 per cent), where in both normal and fœtal livers ethionine inhibits about 90 per cent of the normal protein degradation. This difference is probably due to a different concentration of the proteolytic enzymes susceptible to anti-amino-acid in the tissues examined. It is also important to note that ethionine inhibition of protein degradation in fœtal liver is quantitatively the same as that observed in normal liver. This result is in contrast with the observations reported by Yakovlev[6] on the negative effect of dinitrophenol on fœtal liver autolysis. But it must be remembered that Yakovlev studied the autolysis of homogenates, whereas in the present case intracellular degradation is observed in tissue slices : this difference in the experimental conditions may explain the observed variations in Yakovlev's and my results.

Presence of Œstrone, Œstradiol and Œstriol in Extracts of Ovaries of Laying Hens

GUSTAVSON[1] found a high œstrogenic activity in excreta of laying hens. Others[2] have found activity in ovaries and greater activity in maturing follicles. Hurst[3] has found œstriol and œstrone in excrement of hens, and œstriol, œstrone and œstradiol in that of roosters. The present communication describes the identification of œstrone, œstradiol and œstriol in ovarian tissue of the fowl and the results of a search for their presence in blood.

Ovaries were removed from laying white Leghorn hens. Follicles larger than about 5 mm. diamete. were slit open, and yolk material was discarded. Ovaries with follicle walls attached were weighedr immersed in methanol, and disintegrated with a Waring blendor.

Œstrogens were extracted as described by Mitchell and Davies[4] for human placenta. Residues from final extractions were taken up in a small volume of warm 90 per cent ethanol and stored for 18 hr. at −10° C. The supernatant was concentrated and chromatographed. Preliminary fractionation into œstriol and œstrone–œstradiol fractions was omitted.

Chromatography was performed on Whatman No. 1 filter paper and an absolute methanol – petroleum ether system at 34° ± 1° C. was used[5]. Good separation of reference œstriol, œstradiol and œstrone was obtained with a 6–10 hr. run, provided that strips were dried in an oven immediately before application of the steroids, and were then immediately placed in the chromatography chamber for equilibration.

Narrow strips cut from the developed chromatograms were immersed in freshly prepared diazotized sulphanilic acid and then in 1·1 per cent sodium carbonate. The yellow spots formed indicated the positions of the œstrogens. The steroids were eluted into ethanol, and the ultra-violet absorption spectra were examined on a recording spectrophotometer. Identifications of œstrone and of œstradiol were confirmed by 'finger-printing' with reference steroids labelled with carbon-14 (Chas. Frosst and Co., Montreal). The steroid labelled with carbon-14 was added to a sample of the presumptive œstrogen isolated from ovarian tissue in the estimated ratio 5 : 1 (carrier to labelled steroid). The amount of labelled material used was 5γ, which gave a barely perceptible stain with diazotized sulphanilic acid reagent. The mixture of labelled and presumptive steroid was chromatographed and the strip was stained and then exposed for three days on X-ray film. Complete coincidence of stained spots with spots on the radioautograph in respect of shape and position was taken as positive identification of presumptive œstrogen with labelled steroid. Three spots, positive to diazotized sulphanilic acid and to Kober reagent, were located on chromatograms of extracts of 'free' œstrogen fractions obtained from ovarian tissue. Mobilities were similar to those of œstriol, œstradiol and œstrone on reference chromatograms, and their ultra-violet absorption spectra agreed with those of the appropriate reference œstrogens. Results of the radioactive 'finger-printing' of the presumptive œstrone and œstradiol are shown in Fig. 1. Chromatograms of the 'conjugated' and 'protein-bound' fractions of ovarian extracts contained small amounts of material positive to diazotized sulphanilic acid, but individual œstrogens were not found in these fractions.

A ketosteroid described previously[6] was found in all extracts of ovaries and of blood from laying hens. The results of bioassays conducted on eluates of the ketosteroid indicated no œstrogenic activity. Neither œstradiol nor œstriol was located in any of the fractions of an extract from 650 ml. of blood from laying hens. A compound either identical with, or very similar to, œstrone was located in the 'conjugated' fraction of the extract. A ketosteroid described previously[6] was found both in 'free' and 'conjugated' blood fractions. This material was recovered by dialysis[6] from 50-ml. samples of blood from laying hens, but it was not found on chromatograms of similar extracts of 50 ml. blood from male or immature female fowl.

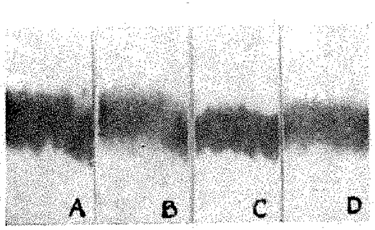

Fig. 1. Radioautographic 'finger-printing' of presumptive œstrogens from avian ovarian tissue.

(*A*) Spot on radioautogram of chromatogram of presumptive œstrone mixed with 5γ of œstrone labelled with carbon-14.

(*B*) Spot on same chromatogram stained with diazotized sulphanilic acid

(*C*) Spot on radioautogram of chromatogram of presumptive œstradiol mixed with 3γ of 17-β-œstradiol labelled with carbon-14.

(*D*) Spot on same chromatogram stained with diazotized sulphanilic acid

The results provide evidence, based on chromatographic mobility, ultra-violet spectrophotometry and chemical reaction, that the main œstrogens elaborated by the avian ovary are œstrone, œstradiol and œstriol. The identity of the presumptive œstrone and œstradiol with the reference compounds labelled with carbon-14 was established by the radioautographic 'finger-printing'. The identity of the chromatographic mobility of the presumptive œstriol with that of the reference sample, coupled with its ultra-violet absorption spectrum and positive Kober reaction, constitute strong evidence that the material isolated from avian ovaries was œstriol.

We wish to thank the National Research Council of Canada for a grant which made this work possible, and Dr. J. F. Sykes, of the Agricultural Research Service, Beltsville, Md., for carrying out the bioassays. The investigation was supported by a research grant from the National Research Council of Canada.

Effect of Thiosemicarbazones on the Multiplication of Tobacco Mosaic Virus

While much effort has been expended on the chemotherapy of plant virus diseases[1], it seems to provide no conclusive evidence. Iwasaki *et al.*[2] obtained marked inhibition of influenza and Newcastle virus by thiosemicarbazones and related compounds. We have performed tests to determine the effect of certain of the thiosemicarbazone derivatives on the multiplication of tobacco mosaic virus in detached tobacco leaf tissues.

The strain of virus used was the ordinary strain found in Japan. Unsubstituted thiosemicarbazones from benzaldehyde, acetophenone, cinnamaldehyde, and benzalacetone and some of the para-substituents (nitro-, dimethylamino-, amino- and acetylamino-) of them were tested. The derivatives employed were obtained through the kindness of Dr. Tamio Nishimura of the Kitasato Institute, Tokyo. All

Table 1. INHIBITION OF MULTIPLICATION OF TOBACCO MOSAIC VIRUS BY THIOSEMICARBAZONES

* Analysed by ammonium sulphate method; † by trichloracetic acid method. Figures represent the average values of 2–3 independently treated samples.

the compounds were dissolved in a small amount of acetone and were filled up to a desired volume with distilled water. Each compound was used at a concentration of 10–50 μgm./ml. The detached tobacco (*Nicotiana tabacum*, Turkish) leaves were inoculated by rubbing with a gauze pad soaked in tobacco juice infected with mosaic virus and were maintained in an incubator for 24 hr. at 25° suspended on water. Then the leaf-halves or leaf disks (12 mm. diam.) cut from the inoculated leaf were floated in continuous light (daylight fluorescent lamps) on aqueous solutions of the test compounds; the opposite leaf-halves or other disks floating on water served as controls.

After 6 days incubation, the leaf tissues were homogenized and analysed for the virus. Two analytical methods were tried. One consisted of precipitating virus protein by ammonium sulphate and then determining the relative concentration of the resultant precipitates by a colorimetric procedure using the Folin reagent[3]. The other method, in which usually 20 leaf disks (0·5–0·6 gm.) were used, was the combination, according to Bancroft and Curtis[4], of the chloroform–water emulsion technique and the trichloracetic acid method for precipitating and hydrolysing tobacco mosaic virus. In the latter case, the virus was assayed by spectrophotometric methods of measurement at 260 mμ.

Thiosemicarbazones, with or without para-substituents, were tested at first (Table 1). The compound most effective in producing inhibition was benzalacetone thiosemicarbazone both in the analysis by the ammonium sulphate method and by the trichloracetic acid method. Furthermore, in this case, the unsubstituted compound was most effective, indicating that introduction of a nitro-, amino-, dimethylamino-, or acetylamino-group at the para-position of the benzene nucleus diminishes the inhibitory activity. Among the para-substituents of benzalacetone thiosemicarbazone, however, it seemed likely that dimethylamino and acetylamino substituents exhibit a considerable inhibition by the analysis of the ammonium sulphate method, but not by that of the trichloracetic acid method. Accordingly, both dimethylamino- and acetylamino-para-substituents of benzaldehyde and cinnamaldehyde thiosemicarbazones were tested and were compared with the unsubstituted ones. From these results it is evident that these compounds do not show any detectable increase in inhibitory activity when analysed by the trichloracetic acid method. Although acetophenone thiosemicarbazone inhibited markedly, according to the trichloracetic acid method, the multiplication of the virus, it produced comparatively severe toxicity to host leaf, and these observations cannot be accepted without question. Iwasaki *et al.*[2] have reported that unsubstituted benzalacetone thiosemicarbazone is most effective against influenza viruses, *PR*8, *FM*1 and Lee strains, and Newcastle disease virus. In this respect, these results are well in accord with those obtained with the plant virus.

Sensitivity of the Spermatogenic Process in the Rat to Radiomimetic Drugs and X-Rays

SPERMATOGONIA are considered to be the most radiosensitive cells of the male germinal epithelium. They may be selectively damaged or destroyed without apparently impairing the continued development into spermatozoa of later generations of spermatogenic cells present at the time of irradiation. In the mouse, Oakberg[1] has found that exposure to 200 r. rapidly destroyed all type *B* spermatogonia, and Bateman[2] observed a transient sterility in male mice six weeks after exposure to this dose which was associated with marked oligospermia. These two findings are correlated and provide an estimate of the overall time required for the development of spermatozoa in the seminiferous tubules (testicular phase) and their transport through the epididymis (epididymal phase). Other results from radioactive tracer experiments in the mouse[3] have also indicated a period of about 40 days for the same process. Since Oakberg[4] has proposed that five weeks (34·5 days) are required for the testicular phase of spermatogenesis in the mouse, it follows that an additional week is occupied by the epididymal phase.

In rats after 200 r. (whole-body irradiation) the only significant change we have observed during nine weeks of consecutive weekly matings was a reduction in average litter size during the fourth and fifth weeks (Fig. 1). There was no noticeable oligospermia. After 500 r. given either as a single dose or five daily exposures of 100 r., rats did not become sterile until the seventh week, although the average litter size dwindled progressively in previous weeks (Fig. 2). The onset of sterility was accompanied by pronounced oligospermia, and the sterile state persisted for at least three months. In the mouse, it is well known that prolonged sterility after 500 r. commences in the fourth week; according to Auerbach[5], this is due to the destruction of spermatocytes as well as spermatogonia. These comparative results suggest the following conclusions: (*a*) the radiosensitivity of corresponding cells in the mouse and rat are markedly different, and/or, (*b*) the overall

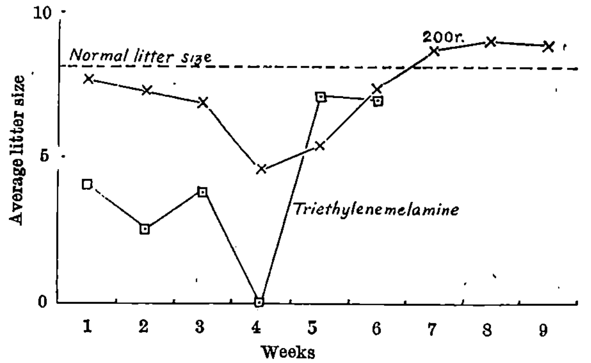

Fig. 1. Effect on male rat fertility of a single dose of triethylenemelamine (0·2 mgm./kgm., intraperitoneal) compared with one dose of X-irradiation (200 r., whole-body)

time for spermatozoa to develop in the testis and appear at insemination is considerably longer in the rat than the mouse.

If the radiosensitivity of cell types is comparable in the two species, then sterility in the fourth week in the mouse corresponds to the seventh week in the rat. On the other hand, recent publications suggest that the duration of the testicular phase in mouse and rat are similar; this will relate differences in the total time to that required for the passage of sperm through the epididymis. From a study of the progression of injected radio-opaque material through the rat epididymis, MacMillan and Harrison[6] have suggested that the duration of this phase is 12–16 days.

We also made detailed examinations of the effects of radiomimetic drugs (and related compounds) on the fertility of male rats. It is our experience that these substances can produce well-defined periods of sterility which are indicative of selective actions on various stages of spermatogenesis[7]. For example, for triethylenemelamine the most susceptible phase corresponds to a period of sterility in the fourth week after a dose (Fig. 1). This finding was previously correlated with drug action on spermatogonia[7], but no allowance was made for the epididymal phase. Infertility in the fourth week after giving triethylenemelamine now appears to be the result of interference with a later stage of spermatogenesis. The ability of a short course of this drug to produce a sterile period lasting for several weeks from treatment, followed by rapid recovery six weeks later, contrasts with the onset of prolonged sterility in the seventh week after 500 r. (Fig. 2). It is tempting to infer a significant correlation between the time relationships of these effects.

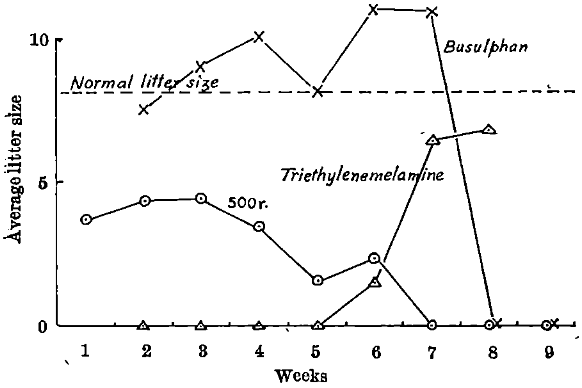

Fig. 2. Comparison of the effects on male rat fertility of triethylenemelamine (five daily doses, 0·2 mgm./kgm., intraperitoneal), X-irradiation (500 r., whole-body) and busulphan (one dose, 10 mgm./kgm., intraperitoneal)

We have also found that busulphan (myleran) has a well-defined action on rat fertility. This radiomimetic drug, unlike triethylenemelamine and radiation (500 r.), had no effect on size of litter until the eighth week after a single dose (Fig. 2), when sterility developed with remarkable rapidity. This change was also associated with the onset of oligospermia (as with 500 r.) and is consistent with the destruction of early germinal cells. Since the rats were fully fertile 45 days after the dose but sterile a week or so later, it may be that the overall time for sperm development and their appearance at copulation is even longer than has been supposed.

Comparable experiments in the mouse are in progress, and also histological studies in both species.

Isolation of the Lethal Factor of Diphtheria Toxin by Electrophoresis in Starch Gel

Highly purified toxins of *Corynebacterium diphtheriae* have been shown to be very complex mixtures by antigen–antibody diffusion in gelatin[1]. In spite of their apparent homogeneity as determined by filter paper electrophoresis, one of us demonstrated the complex nature of such toxins by electrophoresis and immunoelectrophoresis in starch gel[2]. All the crude, as well as the crystalline, toxins (a generous gift of Dr. C. G. Pope) screened by these methods (Poulik, in preparation), have invariably shown the presence of two major components in addition to many minor ones. Since diphtheria toxin is lethal in very high dilutions for guinea pigs, it was assumed that it is most probably one of the two major components which is the cause of death.

Diphtheria toxin *TD*-3-51 (kindly given by Dr. Inge Scheibel, Statens Serum Institute of Denmark), was produced on a tryptic digest of beef muscle medium[3,4] and contained 162Lf./mgm. (0·084 mgm. total N/mgm.; 0·069 P–N/mgm.). This material was subjected to starch gel electrophoresis[5] in a discontinuous system of buffers (*tris*-citrate in the starch gel and sodium hydroxide/boric acid in the electrode vessels[6]). This combination of buffers resolved the two major components very well and thus assured their purity.

Fig. 1 shows diagrammatically the result obtained. After electrophoresis the gel was cut into blocks 1 cm. wide and the proteinous materials contained in these blocks were removed by squeezing the sponge-like starch blocks after freezing and thawing. The

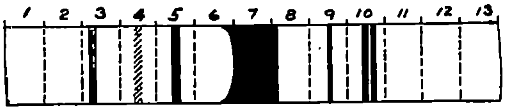

Fig. 1. Starch gel electrophoresis in discontinuous system of buffers, at 6 V./cm. for 5 hr. Material: Toxin-*TD*-3-51, 162Lf./mgm., 0·084 mgm. total N, 0·069 P–N/mgm.

toxicity of these solutions was tested on guinea pigs (250–300 gm.) by injecting 0·1 ml. intradermally. The material obtained from section 7 killed the animal in 1 : 1,000 dilution in four days or sooner and produced a typical skin reaction at dilution 1 : 100,000. The solution from section 5 killed the animal only when injected undiluted and produced a typical skin reaction at a dilution of 1 : 1,000. Autopsies performed on animals killed by the materials in sections 7 and 5 revealed pathological findings typical for diphtheria (hæmorrhage into adrenals; pleural effusion; congestion of the wall of the gut). Toxin recovered from section 5 produced a much larger area of necrosis at the site of injection. This activity and the slower rate of migration are the only criteria, at the present time, which make us feel that this is a different substance as compared with material in section 7. It has not yet been possible to obtain a conclusive demonstration that this component is a separate immunological entity.

It was concluded that the most potent lethal factor of the toxin of *Corynebacterium diphtheriae* was isolated in section 7. This component is not a single protein since starch gel immunoelectrophoresis[3] had demonstrated at least two and possibly four lines of flocculation in this area, two of them intersecting and thus further indicating the complexity of this fraction. Material from section 5 was also found to be heterogeneous. It was also shown experimentally that more than one lethal factor is present in the toxins grown in culture media, and that each of these is again a mixture of proteins, presumably with different enzymatic activities, such as hæmolysin, deoxyribonuclease[7], transferrin-splitting factor (Poulik, unpublished work), a possible mucopolysacharidase[2], hyaluronidase and a necrotizing factor[8], to mention just a few. Since any of these enzymes, and possibly others, may be present in either of the electrophoretic components described, speculation on the mode of action of diphtheria toxin is not justified until all the biologically active factors present are determined.

The opinion of O'Meara[9] and that of Niggemeyer[8], that the diverse clinical courses of the disease could be explained on the basis that several such factors are in operation either singly or in combination, is shared by us. Recent experiments described by Yoneda and Pappenheimer[10] on the production of extracellular products released by certain non-toxigenic strains of *C. diphtheriae* and a toxigenic strain derived from them by infection with a bacteriophage, showed the way of approach to such a problem. Since clinical cases exist (hypertoxic diphtheria) where administration of commercial antitoxins fails to control the course of the disease[8,9], the question remains what antigen or antigens should be used for preparation of antisera which would be able to cope adequately with all the toxic materials regardless of their type or quantity.

This work was supported by a grant awarded by the Department of National Health and Welfare. We are indebted to Dr. Milton H. Brown for his interest and to Dr. Frieda Fraser and Dr. D. A. Scott for reading the manuscript.

Mode of Action of Organophosphorus Insecticides

It is widely held that organic phosphates exert their insecticidal action by the inhibition of cholinesterase activity in the nervous system. Definite proof of this theory, however, has never been furnished and some years ago doubt as to its correctness was expressed by Hopf[1] and also by Lord and Potter[2].

According to many investigators, there is an excess amount of cholinesterase in the nervous system of mammals, and toxic effects will only be seen after more than 80 per cent inhibition of enzymic activity. The occurrence in such an excess is quite a normal feature of enzymes. Assuming that the cholinesterase present in insects is essential for some vital function of the organism, possibly for conduction in the nervous system, one might expect poisoning symptoms to occur only when the cholinesterase activity is strongly inhibited. It should not be overlooked that, in order to prove that a substance derives its toxicity from the inhibition of some enzyme, it is necessary to show, (1) that it has a strong inhibitory action on the enzyme *in vitro*, and (2) that this enzyme in the living insect is actually inhibited at the time that symptoms of intoxication appear.

Our investigations were carried out largely with O,O-dimethyl-O-2,2-dichlorovinyl phosphate, which is very toxic to houseflies (*Musca domestica*; *LD*50< 0·1 µgm./gm.). The inhibitory action of this substance on housefly cholinesterase *in vitro* is about a hundred times that on horse-serum or mouse-brain cholinesterase and twice that of paraoxon on housefly cholinesterase. At a rough estimate, only 0·5–1·5 mol. of O,O-dimethyl-O-2,2-dichlorovinyl phosphate per mol. (active group) of enzyme is required to give 50 per cent inhibition. It is clear, therefore, that inhibition of cholinesterase could be the reason for its toxicity. However, it is also a very potent inhibitor of other esterases, especially in the housefly. One of these ali-esterases, present mainly in the thorax and clearly distinct from the cholinesterase which is chiefly found in the head, was able to split methyl butyrate at considerable speed *in vitro* and proved to be inhibited by approximately the same concentrations of O,O-dimethyl-O-2,2-dichlorovinyl phosphate as the cholinesterase; so its toxicity could also be due to inhibition of this ali-esterase. It was of interest, therefore, to investigate the inhibition, *in* *vivo*, of both enzymes at the time intoxication appeared.

Inhibition of cholinesterase *in vivo* was measured in the following way. Houseflies were exposed to O,O-dimethyl-O-2,2-dichlorovinyl phosphate vapour. Poisoning symptoms such as hyper-excitation and convulsions occurred after some time and eventually the flies were knocked down. A simple device enabled us to remove each individual fly from the experimental glass as soon as this stage of intoxication was reached. The flies were then, until further treatment, kept in a test-tube chilled by a mixture of ether and solid carbon dioxide. When all the flies had been collected they were quickly transferred to a flask containing bicarbonate-saline and acetylcholine (acetylcholine $1 \cdot 5 \times 10^{-2}$ *M*) and homogenized. The suspension obtained was immediately used for measurement of cholinesterase activity in the Warburg apparatus—at 37° C. and *p*H 7·4 (bicarbonate–carbon dioxide buffer), without any further addition of acetylcholine—and compared with a control suspension of untreated flies. It contained about 3×10^{-9} *M* O,O-dimethyl-O-2,2-dichlorovinyl phosphate, which in other experiments was found to cause more than 90 per cent inhibition after 1·5 hr. of incubation without protection by acetylcholine. The addition of acetylcholine to the saline in which the flies were homogenized was necessary to prevent any O,O-dimethyl-O-2,2-dichlorovinyl phosphate present in the tissues but not yet irreversibly bound to the enzyme surface, from attacking the enzyme; especially since we have shown (Fig. 1) that O,O-dimethyl-O-2,2-dichlorovinyl phosphate readily reacts with the cholinesterase, forming an inactive complex and thus producing inhibition. After addition of acetylcholine, however, no further increase of inhibition occurs, the enzyme being then completely protected by the substrate molecules. This was confirmed by several experiments in which rather high concentrations of O,O-dimethyl-O-2,2-dichlorovinyl phosphate were prevented from exerting inhibitory effects by the presence of acetylcholine in a concentration normally used in our experiments. As a consequence of the method used, the enzymatic reaction started about 25 min. before measurement in the Warburg-apparatus could be undertaken. We therefore investigated the possibility of reactivation of the enzyme, especially as Aldridge and Davison[3] have shown that the inhibition of cholinesterase from rabbit erythrocytes by dimethylphosphates is slowly reversible. We found that there was no reactivation at all in the case of housefly cholinesterase, although it did in fact occur in the case of mouse-brain cholinesterase.

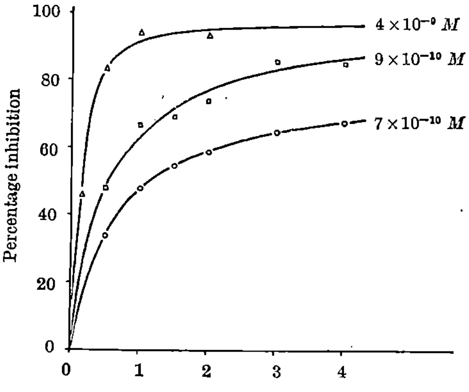

Fig. 1. Inhibition of housefly cholinesterase by O,O-dimethyl-O-2,2-dichlorovinyl phosphate. Incubation time is time available for the reaction between enzyme and inhibitor before the substrate is added

Measurements of *in vivo* inhibition as described above will, in our view, give a very good approximation to the actual inhibition value at the time of knockdown. Essentially the same method has been adopted for the measurement of inhibition of ali-esterase *in vivo*, using methyl butyrate as a substrate. Methyl butyrate, as was shown in several experiments, gives appropriate protection of the ali-esterase against O,O-dimethyl-O-2,2-dichlorovinyl phosphate under conditions such as those of our experiments on *in vivo* inhibition. In a few cases inhibition of cholinesterase has also been measured in heads or thoraces + abdomens, separated just before homogenizing took place. The results of our experiments are shown in Table 1.

Table 1. PERCENTAGE ENZYME INHIBITION AT THE TIME OF KNOCK-DOWN

ChE of whole flies	25, 27, 28, 24, 29, 29 per cent	mean 27 per cent
ChE of the heads	10, 39, 22 per cent	mean 24 per cent
ChE of thor.+abd.	43, 49 per cent	mean 46 per cent
AliE of whole flies	86, 84, 79 per cent	mean 83 per cent

These results are very striking. Although the overall values for inhibition are low, it cannot be excluded that stronger inhibition of cholinesterase activity was occurring at some small but essential part of the nervous system; but we nevertheless consider that the results in Table 1 provide evidence against an essential role of cholinesterase inhibition in the insecticidal action of O,O-dimethyl-O-2,2-dichlorovinyl phosphate. We do not claim that this evidence is conclusive, because it is possible that the results in the literature concerning the excess of cholinesterase present in the organism are incorrect. All the latter results are based on inhibition values *in vivo* which, so far as we know, were obtained without protection of the enzyme against excess of inhibitor and, therefore, are probably too high.

Our findings were provisionally confirmed by experiments on cholinesterase inhibition, in which di-*iso*propylfluorophosphonate, parathion and paraoxon were applied. The strong *in vivo* inhibition of the ali-esterase (splitting methyl butyrate) points to this enzyme and the possible role of its inhibition in the intoxication caused by organophosphates.

Distinction between *Cardium edule* L. and *Cardium lamarcki* Reeve

FROM material gathered by the Danish Institute for Fishery and Marine Research in Danish estuaries I have examined the species of *Cardium* of which there were three types—*A*, *B* and *C*. Type *C* was identified as *C. exiguum*. In the literature the types *A* and *B* are described as varieties of *C. edule*. In my material the two types existed together in some of the estuaries, and they were often found in the same bottom samples, and always without any intermediate types. I have identified type *A* as *C. edule* L. and type *B* as *C. lamarcki* Reeve 1845 [1].

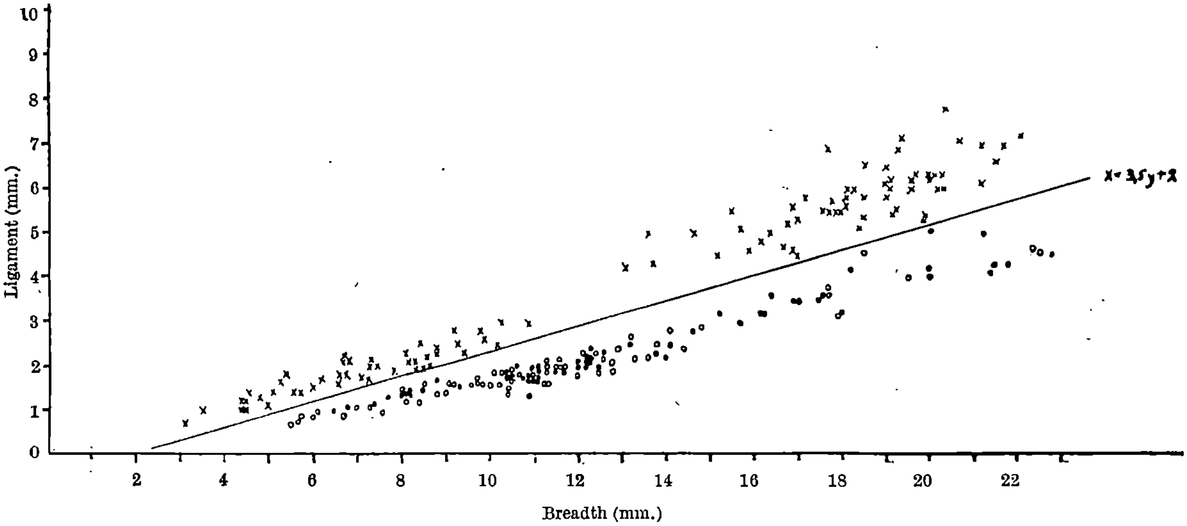

Fig. 1. ×, *Cardium edule*; ○, *Cardium lamarcki*

C. edule and *C. lamarcki* have the following distinctive characters: The ribs on the middle part of the shell of *C. edule* are flat and provided with small scales some distance from each other; in *C. lamarcki* these ribs are sharp and provided with small triangular closely placed scales, formed from the epidermis. The ribs on the posterior part of the shell are fairly well developed in *C. edule* and scarcely developed at all in *C. lamarcki.* Because of this difference the part of the shells around the siphons will close along a wavy line in *C. edule* and along an almost straight line in *C. lamarcki.* The epidermis is very badly developed in *C. edule.* The epidermis of *C. lamarcki* is rather thick and covers about 75 per cent of the surface of the shell. In colour and shape a difference between the two types also exists, *C. edule* being the more whitish and circular one, but as colour and shape vary much, these are not taxonomic characters.

C. lamarcki shows considerable variation, and smaller individuals from the vegetation and brackish water have thin brown shells with flat ribs without scales and broad furrows. This form somewhat resembles *C. exiguum.* At a length of 4–8 mm. they often suddenly change and begin to build the shell with narrow furrows, and sharp ribs with scales. This change in structure may be correlated with a change in habitat, for example, from vegetation to the bottom. *C. lamarcki* is very often found in the vegetation climbing by means of its byssus. I have never seen *C. edule* climbing in the vegetation or using a byssus.

The most distinctive character is the length of the hinge ligament in relation to the breadth of the animal. In Fig. 1 the x-axis represents the breadth of the animal and the y-axis the length of the hinge ligament. The measurements plotted were all made on animals taken from bottom samples in which the two types occurred together. The bottom material was fine sand. In Fig. 1 the two types are clearly separated by the line $x = 3{\cdot}5\, y + 2$. Probably this function will prove to be invalid for the smaller animals, and perhaps the two types are separated by a non-linear function.

In geographical distribution the types are separated also, but they overlap in some localities. Such localities are the mouth of the Mariager Fjord estuary and the Kysing Fjord estuary, both situated at the Kattegat coast of Jutland. The animals used for Fig. 1 are from these localities, in which the salinity is always more than 20 per mille. In more brackish water, as, for example, the innermost parts of Mariager Fjord and Kysing Fjord and the estuaries on the Belt Sea and Baltic coasts, we find only *C. lamarcki,* which tolerates salinities from about 25 to about 5 per mille. *C. edule* does not tolerate salinities lower than 20 per mille. *C. exiguum* is found only in areas with a rather constant salinity about 7–14 per mille.

Quantitative Gram-staining with Labelled Iodine

The development of a simple quantitative Gram-staining technique has been attempted by numerous observers[1,2], not only for its possible practical uses but also because of its potential value in studies on the mechanism of the staining reaction on intact cells and on extracellular material[3], as well as the relationship between degree of Gram-positivity and physiological state of the organisms. The recent procedure of Barbaro and Kennedy[4] is reasonably accurate but, since it involves measurement of dye nitrogen taken up by a suspension of organisms, it is rather laborious for practical application.

Taking advantage of the fact that iodine is co-operatively bound in the Gram reaction, we have developed a reasonably accurate quantitative Gram-staining technique based on the use of 'Lugol' solution labelled with iodine-131, followed by end-window counting of the stained smear on the slide. Our procedure is to stain a heat-fixed smear, containing about 8–13 µgm. dry mass of bacterial cells, according to the Hucker modification[5], the sole difference being that the 'Lugol' solution contains approximately 25 µc. iodine-131/ml. and is applied by means of a 20-µl. micropipette so as completely to cover the smear. Following are typical results for 15-hr. cultures of several organisms (recalculated for 10 μgm. dry mass of each organism on the slide):

Strain	Degree of Gram-positivity (counts/min.)
Bacillus subtilis	2,856
Micrococcus lysodeikticus	1,320
Saccharomyces cerevisiae	1,068
Lactobacillus casei	883
Proteus vulgaris	245
B. coli	78

It will be noted that *Saccharomyces*, one of the most intensely Gram-positive organisms, is apparently less so than *B. subtilis* and *M. lysodeikticus*. This is, however, due to the variation of degree of Gram-positivity with age of culture and, especially, the decolorization technique used. If the decolorization step in the Gram procedure is increased by 1 min., then *Saccharomyces* show a higher count than other organisms.

The reproducibility of the method is about 5 per cent. The following modifications do not influence the final count: (1) two-fold increase in concentration of primary dye; (2) three-fold increase in concentration of the 'Lugol' solution, the specific activity/mgm. iodine being kept constant; (3) variation in time of application of the primary dye, or the 'Lugol' solution, from 15 sec. to 2 min. This is good evidence that the Gram-complex involves stoichiometric proportions of dye and iodine with some cell constituent(s). Decolorization of a stained smear until the count is almost zero, followed by re-staining, gives a count close to that of the original, so that the reaction is completely and quantitatively reversible. Treatment of a labelled smear with aqueous non-labelled 'Lugol' results in complete removal of radioactive iodine without altering the intensity of staining; subsequent application of aqueous labelled 'Lugol' restores the original count of the smear. In alcoholic 'Lugol' solution this exchange phenomenon does not occur. One may therefore conclude that the staining reaction involves co-operative binding of dye and ionic iodine. It is consequently doubtful whether dye fixation by Gram-positive cells is due to oxidation of cellular material by iodine[6]. The suggestion that iodotyrosine is formed upon application of the iodine[7] is rendered untenable by the rapidity with which the iodine in the Gram-complex is exchanged, for the rate of exchange of ionic iodine with the iodine in iodotyrosine is very low and is preceded by a pronounced lag period[8].

We have found the above technique extremely useful for various quantitative studies on Gram-staining, full details of which will be published elsewhere. We should like, however, to emphasize the considerable advantages to be gained from the general application of labelled substances to quantitative staining reactions as well as to the mechanisms of these reactions.

Phototropism of *Phycomyces* Sporangiophores

THE communication to *Nature* concerned with phototropism in *Phycomyces* from Curry and Gruen[1] and its extension by Carlile[2] may be considered in relation to the critical study of the phenomenon of adaptation undertaken by Delbrück and Reichardt[3].

The rate of growth of *Phycomyces* sporangiophores can be regarded as controlled by the supply of materials from the substratum mycelium, but it is influenced in the apical region by an unknown photo-sensitive system. The average growth-rate over a period of hours is independent of illumination, though it has a normal temperature coefficient: light favours earlier sporangium formation, but after that growth continues to an extent and for a duration not noticeably affected by visible light. Increase in intensity of symmetrical illumination with blue light leads, after two to three minutes, to a transient increase in the longitudinal growth-rate, Blaauw's[4] positive light-growth reaction. The rate may increase during the next few minutes to twice normal, then diminishes to less than normal even though the brighter illumination continues, and finally resumes its former rate with no net change in the average rate of growth. The sporangiophore has thus become adapted to a higher light flux. (In this respect its light-growth reaction differs from what appears to be usual in young green shoots.) Decrease in illumination produces a corresponding negative reaction and subsequent adaptation.

Phototropic curvatures arise when the rate of effective photon absorption in one side of the growing zone is appreciably different from that in the other side, leading to asymmetry in growth-rate. On a horizontal clinostat such curvatures continue for as long as spatial asymmetry in light absorption is maintained in the growing sporangiophores. This is quite compatible with the phenomenon of adaptation to changes in flux with time, for, while the distribution of growth-rate is not uniform, the average rate of growth in volume continues unchanged.

Curry and Gruen, remarking on the prompt reverse curvature when their cultures, unilaterally illuminated with ultra-violet light, were rotated through 180°, say that "this implies that there is little adaptation to the ultra-violet, the sensitivity remaining high through many such reversals of position". It may be that there is little adaptation, as could well be determined by observing whether the same intensity of response followed each time when a sporangiophore was first illuminated symmetrically with, say, 0·2 ergs/cm.^{2}/sec. of ultra-violet radiation, and then at half-hour intervals the illumination was increased by successive equal increments of 0·2 erg/cm.^{2}/sec. Without adaptation the same response would follow each time; with, it would diminish. Their conclusion is not, however, necessarily implied by prompt reversibility of the phototropic curvature. Adaptation can be regarded not only in relation to the sporangiophore as a whole but as a property varying in level throughout the growing region according to the light flux at each point. For a sporangiophore uniformly illuminated with blue light the flux throughout the apical zone will vary little. Under unilateral illumination with blue light there are, owing to the lens effect[5], rather more photons absorbed in the far half than in the near, so giving positive phototropism, but the gradient is not steep and the levels of adaptation do not greatly differ. Therefore rotation through 180°, reversing this small flux gradient, results in only small changes in the growth-rates of the two sides (by redistribution of the materials being supplied from below) leading to a sluggish reversal of the positive phototropic curvature. When, however, the sporangiophores are illuminated either along one flank by a grazing pencil of light[6], or unilaterally under paraffin (refractive index, 1·47, giving a complete reversal of the lens effect), or are exposed to unilateral ultra-violet light of about 280 mμ wave-length (for which the absorption coefficient, α, is high), then there is a high rate of photon absorption on the illuminated side and a much lower rate on the other. With such marked differences in flux, and consequently in adaptive levels, rotation of the sporangiophore might be expected to lead to the sharp reversal of curvature found in these cases.

Turning now to the suggestion made by Carlile, it should be pointed out that, while it is true that the curve plotted by him shows a good approximation to the absorption spectrum of riboflavin, there is a danger of error in taking the phototropic curvature of a relatively transparent organ as an index of photodynamic effectiveness when determining the action spectrum. This is because the value of the absorption coefficient, α, changes with wave-length, thus changing the gradient of the corresponding photon absorption per unit volume. This, as Carlile suggests, presumably explains the change from positive to negative phototropism with diminishing wave-length in the ultra-violet.

If with ultra-violet radiation of 302 mμ wave-length there is a positive light-growth reaction in previously darkened sporangiophores, but not phototropic curvature because Castle's critical value for α is reached, then clearly the true action spectrum for a photo-response should not drop to zero as does the graph of angle of phototropic curvature that Carlile plots. A better curve for the primary photo-response could be obtained by the lengthy process of measuring the average light-growth response when passing suddenly from darkness to a standard flux of radiation of each of an extensive series of wave-lengths. With relatively transparent organs there is an inherent error when using either phototropic curvatures or null-deflexion methods with opposed sources of light of different wave-lengths as an index of photodynamic effectiveness. Add to this the probability of ineffective absorption in shadow-producing pigments, of which carotene may be one, and it is clear that great caution should be exercised when such results are compared with known absorption spectra.

Brauner[7] suggested that the positive light-growth reaction and phototropism in *Phycomyces* might arise through partial light-induced destruction of a previously supra-optional concentration of indolyl acetic acid. Results of experiments now in progress, some devised in discussion with him, do not seem to support this suggestion. Lanolin paste and sodium alginate gel containing 10 μgm. and 100 μgm./ml. of indolyl acetic acid have been applied with a micromanipulator to one side of the growing zone of sporangiophores which either (1) had previously been subjected to intense illumination with blue light or (2) were, after indolyl acetic acid treatment, illuminated from the side opposite to that treated. Case (1) sporangiophores after further growth in red light having no phototropic action showed no significant response compared with controls treated with plain paste, and in case (2) the positive phototropic response was not reduced: these experiments need to be extended to cover a wider range of conditions.

Riboflavin may indeed be the photoreceptor in *Phycomyces*, and photo-absorption may either reduce the extent to which it checks indolyl acetic acid oxidation, or even directly promote this oxidation, but this assumption is not yet firmly grounded, and there is as yet no good evidence that internal indolyl acetic acid is a myco-auxin regulating the growth of chitin-walled hyphæ.

The primary purpose of my previous communication[1] was to show that the reversal of phototropism at about 300 mμ reported by Curry and Gruen[2] is explicable in optical terms, and that it was not necessary to postulate a novel photochemical reaction occurring in the far ultra-violet. I also felt that it was useful to point out that Curry and Gruen's results on the relative effectiveness of different wave-lengths when plotted as an action spectrum give a curve similar to the absorption spectrum of riboflavin. I agree with Banbury as to the dangers inherent in this procedure, and realize that observations on the effectiveness of a range of wave-lengths in promoting the light-growth response would, if available, provide a better guide as to the nature of the photoreceptor substance.

Limited Multiplication of *M. lepraemurium* in Tissue Culture

M. lepraemurium causes rat leprosy, which possesses many of the characteristics of the human disease. So far, attempts to culture the causative organism of either disease in bacteriological media or in tissue cultures have not provided convincing evidence of multiplication.

The minimum period required to maintain tissue cultures if the growth of *M. lepraemurium* is to be detected, can be inferred from the generation time *in vivo*. This was found to be 13 days[1,2]. Such relatively long periods of maintenance would result in a changing and variable cell population. On the other hand, since *M. lepraemurium* persists in a stainable form, the bacilli would, even without multiplication, become redistributed among the changing cell population. Previous methods for detecting multiplication, which have usually depended on the distribution of bacilli in tissue cells, are open to errors. To determine accurately, therefore, whether multiplication has occurred, we have had to devise a method for counting the total number of bacilli per culture before and after cultivation.

The obligate intracellular existence of the bacillus within reticulo-endothelial type cells led us to use monocytes in our earlier attempts to culture *M. lepraemurium*, but no multiplication of bacilli was shown even after 80 days. However, bacilli recovered from some of these cultures were still infective[3].

We have now shown that multiplication of *M. lepraemurium* can occur in cultures of tissues obtained from previously infected animals. In a representative experiment the spleen was removed from a mouse infected intravenously 8 weeks previously with *M. lepraemurium* (Douglas strain[4]), and was cut, uniformly, into explants of 1 mm.[3]. The explants were pooled and put out in culture tubes (6 per tube) lined with plasma clot to which was added 1 ml. of medium containing 20 per cent horse serum, 5 per cent chick embryo extract and 75 per cent Hanks's balanced salt solution. Before incubation the tubes were randomized into two groups : (*A*) no addition of antileprous drugs, and (*B*) addition of 100γ streptomycin and 1γ isoniazid, a combination expected, from chemotherapeutic observations of rat leprosy[5,6], to inhibit growth of the organism *in vitro*, and so serve as an essential control. The tubes were incubated at 37° C. in roller drums, and the medium changed twice weekly (all medium kept for counting). After 24 hr. three tubes were picked at random from each group, each was trypsinized, the contents homogenized in a Ten Broeck grinder and the bacilli completely released from cells and dispersed by exposure to ultrasonic vibration. Using a modified Breed technique[7], a count was made of equivalent standard samples of homogenates from each culture. This procedure was repeated at 15 and 29 days, selecting the most healthy cultures. To increase the uniformity of the counting technique the homogenates, after immediate sampling, were stored until the experiment was completed and then, after further dispersal by ultrasonic vibration, new coded samples were prepared and counted again in one operation.

The counts are shown in Table 1. Each mean count of bacilli was obtained from three cultures, from each of which two spreads were made and counted in duplicate. The results show a highly significant increase ($P < 0{\cdot}001$) in the number of bacilli in cultures with no streptomycin or isoniazid, by the fifteenth day of incubation; no further increase occurred in cultures maintained for a further 14 days. There was no increase in the number of bacilli in cultures containing high concentrations of the drugs.

Under these conditions, and using precise methods to determine the total number of bacilli present in each culture, it has, therefore, been possible to demonstrate *in vitro* limited multiplication of *M. lepraemurium* in five experiments. Furthermore, the rate of multiplication *in vitro* corresponds closely to that observed *in vivo* in the mouse. In a personal communication from Dr. J. H. Hanks and his colleagues at Harvard Medical School, Boston, we have learned that substantially similar results have recently been obtained using explanted spleen cells from infected mice. Multiplication has been confined to the initial period of cultivation when the cell cultures are healthy. As soon as the infected cells begin to degenerate, increasing numbers of bacilli will be released and exposed to relatively high concentrations of serum, which have been shown to inhibit their endogenous metabolism[8]. It would seem, therefore, that continued multiplication *in vitro* of *M. lepraemurium* requires a regular supply of healthy cells, preferably in a medium containing low concentrations of serum. Methods for providing these cultural conditions are being investigated. A full account of this work will be published elsewhere.

Table 1. MEAN NUMBER OF ACID-FAST BACILLI COUNTED IN STANDARD SAMPLES FROM HOMOGENIZED CULTURES

	Group *A* cultures	Group *B* cultures
Streptomycin	None	100 γ/ml.
Isoniazid	None	1 γ/ml.
Days		
1	111·0	111·3
15	243·0	105·8
29	235·4	108·5

The 1 per cent limits for the ratio of the mean on day 15 to that on day 1 for group *A* cultures are 1·97 and 2·4. (Counts on the fluid changes were very low and are not included in the table.)

We wish to thank Dr. Ian Sutherland of the Medical Research Council's Statistical Research Unit for the statistical analyses.

The Diatom *Asterionella* in the Krishna Estuary Region

DURING the course of an extensive hydrobiological survey of the Krishna River estuary, standing at the mouth of the northernmost branch of the Krishna River, we noticed that the shore waters and the sea, as far as the eye could see, were coloured deep chocolate brown, and that the intertidal sand was covered with a thick green scum. A sample of the water, taken one mile south of the river mouth, was collected in a bottle of known volume (2½ l.), fixed with formaldehyde and allowed to settle for a day, giving a sediment 30 ml. in volume. On analysis of the sediment by a conventional method (using a Sidgwick–Rafter cell), we found that it contained mainly swarms of diatoms, the majority of which belong to the chain-forming genus *Asterionella* (*Japonica ?*). Other forms like *Biddulphia*, *Thallassiothrix*, *Pleurosigma*, *Fragillaria*, and *Chaetoceros* were also found, but in fewer numbers. The catch represents a total population of 55·568 millions per litre (approximately 55·6 cells/mm.^{3}). Of this *Asterionella* alone accounted for 51·6 cells/mm.^{3}.

The waters of the river emptying into the sea were very low both in salinity and phytoplankton content. The salinity was 0·305 per cent at the mouth of the river, but was as high as 2·69 per cent one mile south of the river mouth. Correspondingly, phytoplankton density also showed an enormous increase from 111 cells/ml. at the river mouth to 55·568 million cells/ml. one mile south of the mouth. In view of the fact that the coloured water contained a very dense population of diatoms of which *Asterionella* accounted for nearly 93 per cent, it is reasonable to believe that the colour of the water was a result of the dense occurrence of *Asterionella*. But to our knowledge *Asterionella* was not previously known to be a causative factor in the production of coloured water.

Bainbridge[1], while considering observations concerning the size, shape and density of marine phytoplankton concentrations, quotes several figures for concentrations of diatoms, chiefly for normal waters, obtained by various workers from different regions. The highest figure he quotes, for *Asterionella*, is 3·6 cells/mm.^{3} and observes that much higher figures of 31·6 cells/mm.^{3} for other naturally occurring diatom densities, as was found by Marshall and Orr[2] in the waters of Loch Striven for 1927, must be considered localized and of limited duration. The densities found by us, when compared with the findings of other workers, referred to by Bainbridge, do not appear to be abnormal for highly coloured water with localized concentration of diatoms.

Such high densities in this particular region and the particular time are probably due to the enrichment of the area of the sea water, near the river mouth, by nutrient salts from the mainland through the agency of the flooded river during the north-west monsoon, which sets in during the latter half of June and continues until early October.

We wish to express our grateful thanks to Dr. Kandula Pampapathi Rao, Sri Venkateswara University, under whose general direction the hydrobiological survey is being carried out, and to Mr. Ch. Srinivasa Rao of Dintimeraka and his local associates for help and co-operation in collecting material.

2,4-Dichlorophenoxyacetic Acid as an aid to Seed Production when widely separated *Solanum* Species are crossed

After repeated unsuccessful attempts to duplicate Swaminathan's[1] technique for overcoming the cross incompatibility between *Solanum* species, a study was undertaken to determine the causes of seed failure when widely separated *Solanum* species are crossed. This work showed that some pollen germinated in all attempted crosses between several tuber-bearing series of the genus. Apparently normal pollen tubes were even observed at the bases of *S. melongena* L. styles when that species was pollinated by *S. phureja* Juz. and Buk.

The work indicated that a failure in seed production following the crossing of widely separated *Solanum* species could be a result of a failure in fruit formation because too few seeds were present to stimulate growth of the ovary. Without fruit formation to provide the normal environment for development, the few seeds present would be unable to mature. Therefore, attempts were made to devise a method for stimulating ovarian development which would not itself inhibit seed formation. It was found that treating the ovaries 24 hr. after pollination with a drop of 3–6 p.p.m. of 2,4-dichlorophenoxyacetic acid (2,4-D) had the desired effect.

The results obtained from the cross of a diploid hybrid (*S. chacoense* Bitt. × *S. rybinii* Juz. and Buk.) × *S. stoloniferum* Schlecht., illustrate the value of the treatment. Several hundred attempted crosses of this parental combination yielded only three or four very small berries from the non-treated ovaries, whereas several hundred berries were produced by those treated with 2,4-dichlorophenoxyacetic acid. The berries from the non-treated fruit produced no seeds, but thousands of viable seeds were produced by the treated fruit. By means of this technique, viable seeds have also been obtained from several other wide crosses, and selfed seeds were obtained from hybrid clones of very low pollen fertility. Similarly, Fischnich and Lubbert[2] have reported that 2,4,5-trichlorophenoxyacetic acid was useful for producing seeds from difficult intervarietal crosses. However, these studies have shown that higher concentrations of the di- than of the tri-chlorophenoxyacetic acid were necessary to induce fruit formation in *Solanums*. Moreover, the indications were that the optimum concentration of the latter was sometimes inhibitory to seed formation. The full results of these investigations are being published elsewhere.

Colour Vision of Three Albinos

In 1951 an albino woman was given anomaloscope tests[1] and it was reported that she had a marked deviation in red vision. Recently, two albino men have been tested. The three subjects are unrelated. Tables 1 and 2 indicate the abnormalities of colour vision found in them on the anomaloscope[2].

Table 1. Red–Green Test

Subject's sex and age	Deviation	Matching range
f; 50	6 × sigma to red*	1 × mode*
m; 25	4 × sigma to red	5 × mode
m; 51	8 × sigma to red	5 × mode

* Both tests, about 3 weeks apart

Table 2. Yellow–Blue Test

Subject's age and sex	Deviation	Matching range
f; 50	2 × sigma to yellow	<1 × mode
	<1 × sigma to blue*	<4 × mode*
m; 25	1 × sigma to yellow	4 × mode
m; 51	zero	>2 × mode

* Second test, about 3 weeks later

It will be seen that all three albinos had red deviations almost equivalent to simple protanomaly, while the two men also had enlarged matching ranges, but not quite large enough for them to be classed as extreme protanomals. In none of them was the red end of the spectrum shortened. It is invariably shortened in extreme protanomalous but not invariably in simple protanomalous subjects.

In the yellow–blue test the two men had large matching ranges. The woman had no defect on her first yellow–blue test except a small deviation to yellow, although she was more than fifty years of age; but on her second test she had an enlarged matching range and a very slight blue deviation.

The two men passed the Ishihara test, the younger making only one error. The elder made only four errors. He claimed to smoke seventy cigarettes a day. The woman, although she was less defective than the men, failed on the Ishihara test, with fifteen errors in twenty-four plates.

Moving Visual Images produced by Regular Stationary Patterns

IT would seem that some of the intriguing visual phenomena discussed by Dr. MacKay[1] may be due, not to cerebral or retinal factors only, but at least in part to preretinal factors, namely, fluctuations of accommodation combined with lack of axial symmetry in the optical system of the eye. Helmholtz[2] described how, when looking at a pattern consisting of black and white concentric circles, and thus similar to one of Dr. MacKay's, a complicated system of darker and brighter radial zones is seen. If accommodation, or the distance from the pattern to the eye, is slightly altered, the positions of the brighter zones vary and the observer sees them rotate rapidly to and fro. According to the above explanation the phenomenon is due to actual changes occurring in the image of the pattern formed on the retina. Unless such changes can be ruled out as a factor in Dr. MacKay's more complicated experiments, it does not seem possible to conclude that subjective impressions of movement received while the pattern is looked at, or in after-images, are necessarily caused by the nervous system responding to a truly stationary light distribution in the optical image formed by the eye.

M. H. PIRENNE

University Laboratory of Physiology,
Oxford.

[1] MacKay, D. M., *Nature*, 180, 849 (1957).

[2] Helmholtz, H. von, "Physiologische Optik", 1st ed., Part 1 (1856).

WHILE viewing the pattern of concentric circles reproduced in *Nature* of October 26[1], many readers will have noted rapidly fluctuating sectors and they may have speculated about their cause.

This effect was first described by Helmholtz[2], but although he attributed it to accommodation, he did not give a definitive explanation of why the sectors appear to rotate.

When the young emmetrope focuses on a near test object the amount of accommodation exerted is not constant. The lens is constantly undergoing small (± 0·1 dioptre), rapid (2–3 c./s.) fluctuations of power. This has been demonstrated objectively with an infra-red high-speed recording optometer[3] (see Fig. 1). Arnulf *et al.*[4] have shown that these fluctuations are mainly astigmatic, that is, different segments of the circular ciliary muscle probably contract asynchronously. There are, therefore, even in the emmetropic eye, small, variable astigmatic errors that occur in constantly changing meridians. Inspection of Dr. MacKay's Fig. 2[1] clearly shows rotating sectors. The frequency of occurrence of the effect agrees with the objective measurements shown in Fig. 1 herewith. The reader can readily confirm that the cause of these rapidly rotating sectors is irregular fluctuations of accommodation. The rotation ceases if the eye is focused at infinity. This experiment may easily be done by viewing the pattern at 25 cm. or so through a +4 dioptre lens. Similarly, the rotation stops if the ciliary muscle is paralysed with homatropine eye drops. Naturally, the effect will not be reported by a presbyopic observer who is over the age of fifty-five years. The effect will also cease if the pattern is viewed through a 1-mm. artificial pupil, for the increased depth-of-focus of the eye eliminates the perception of the small variable astigmatic errors[5].

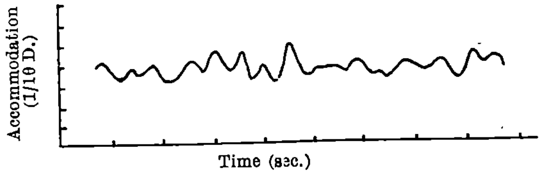

Fig. 1. Variation of power of accommodation measured in the vertical meridian of the eye during steady fixation of a small object (scale in 1/10 dioptre)

F. W. CAMPBELL
J. G. ROBSON

Physiological Laboratory,
Cambridge.

[1] MacKay, D. M., *Nature*, 180, 849 (1957).

[2] Helmholtz, H. von, "Handbook of Physiological Optics", 1, 192 (Optical Society of America translation) (1924).

[4] Arnulf, A., Dupuy, O., and Flamant, F., *C.R. Acad. Sci., Paris*, 232, 349, 439 (1951).

[5] Campbell, F. W., *Optica Acta* (in the press).

THE phenomenon mentioned by Dr. Pirenne is one of several side-effects of our patterns which are being separately investigated because they seem to be distinct from the complementary response. Helmholtz's "rotating sectors" are, of course, well known and may be considered as moiré fringes due to the superposition of displaced replicas of the pattern either in the optical image or at a neural level or both. In the 'ray' figure described in my previous communication[1] similarly fleeting 'figure of 8' moiré patterns can be seen as accommodation varies. The simplest way of demonstrating their origin is to cover the stimulus figure with a transparency of itself, when similar fringes appear (Fig. 1), and one can in fact measure the amplitude and direction of the effective retinal image-displacement by observing the displacement required in the transparency to produce the same moiré pattern.

The marked differences observed between these moiré patterns and the complementary images provided the first reason for believing that the latter had a different origin. The evidence[1,2] of interocular transfer, especially in random visual noise, and of the limited relevance of eye movement demonstrated by the persistence of the response with a stabilized retinal image and in stroboscopic light, combine to confirm that the complementary image presents a different and separable problem. Furthermore, following Campbell and Robson's helpful suggestion, I have verified that the complementary image is still seen when the ciliary muscle has been paralysed by homatropine. It can be seen also (by seven out of

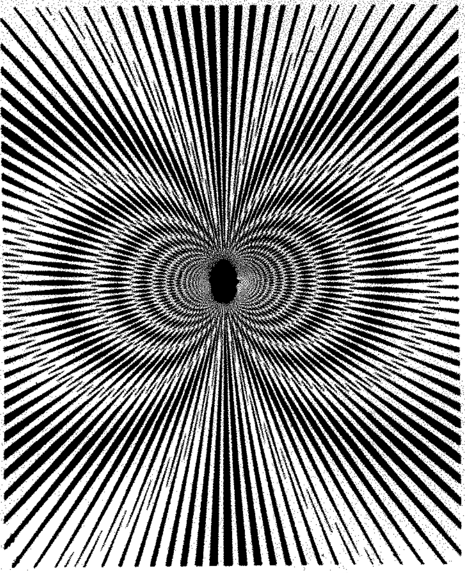

Fig. 1

ten observers to date) in the first few seconds after exposure of the ray-pattern in a single 120-Joule flash lasting less than 1½ msec.

Finally, when the retinal image is deliberately moved in such a way that no moiré figures are generated (for example, by slightly rocking the ray figure about its centre several times per second), the complementary after-image is strengthened (presumably because 'on' and 'off' receptors are stimulated), whereas with other types of artificial motion it is not.

The foregoing evidence would appear to dispose also of a confusion in some early literature[3] between these complementary after-effects and the after-effects of seen movement, caused by the use of striped curtains and the like as moving stimuli. This work, to which my attention has been directed since my earlier communications were published, includes unmistakable reports of complementary images; but writers usually assimilate them to the 'streaming' after-image of movement which they were studying. If one uses a random dot pattern (for example, a photograph of sandpaper) as the moving stimulus, the two effects can be clearly separated.

One interesting side-effect which we are studying is an apparent disturbance of the accommodation reflex by the circular pattern. A hair laid obliquely across its central region may sometimes defy all efforts to bring it into sharp focus, although against a plain background at the same distance it becomes perfectly sharp. It is hoped that experiments in this connexion may yield some clues to the organization of the detector-system which normally enables an out-of-focus image to be corrected.

A fuller account of investigations using these regular stimulus-patterns will be published elsewhere.

Coffinite in Cornwall

Coffinite, $U(SiO_4)_{1-x}(OH)_{4x}$, a rare mineral previously reported only from the Colorado Plateau, United States[1], and the Buller Gorge area of South Island, New Zealand[2], has been identified in ore samples from Roskrow United Mine, Ponsanooth, Cornwall.

Here coffinite occurs as a replacement of colloform pitchblende. All stages of replacement occur from incipient alteration along radial fractures and concentric growth bands to complete colloform pseudomorphs measuring up to 5 mm. across.

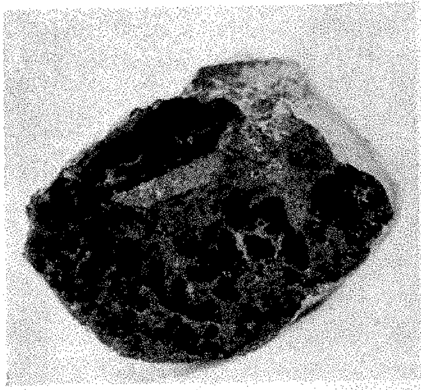

Fig. 1. Colloform aggregates of coffinite (black, lower part of specimen) pseudomorphous after pitchblende. × 0·85

The identification was based on X-ray powder photographs with the strongest lines at 3·49 (v.s.), 4·66 (s.), 2·64 (m.s.) and 1·80 (m.s.) A. A spectrographic analysis showed major uranium and silicon with vanadium and lanthanum among the minor elements.

A full description of the physical properties with a complete chemical analysis will be published elsewhere. The present communication is published by permission of the Director of the Geological Survey.

Subjective Probability, Gambling and Intelligence

It is well known that subjective ideas of probability differ from predictions made using statistical laws. This has been shown in temporal predictions by Jarvik[1], Cohen and Hansel[2] and others. It has also been shown by me[3] to be the case for predictions about spatial ordering.

It is also well known that persons in general like to gamble. If they have the choice of a number of different courses of action which, on the average, will yield the same benefit, they will prefer to risk some loss in order to chance some gain, rather than to choose a course which has a certain outcome. This preference has been shown in laboratory studies by Edwards[4].

The present communication is concerned with the relation between these two phenomena and intelligence.

I set persons the task of searching for an object which might be in one of a number of places, and related the strategy they adopted to their intelligence. This task could either be carried out systematically, or the person could gamble, he could work at 'random', pitting his confidence in his hunches against the risk of forgetting where he had looked. (The advantage of approaching this task systematically is that it ensures no moves will be forgotten.) Forty subjects were each given three problems; eighteen of them always worked systematically. When they were ranked according to their intelligence test scores, it was found (using Whitfield's[5] method) that these eighteen were of significantly higher intelligence than the rest ($p < 0{\cdot}002$, two-tailed test).

The results posed a question. Did the more intelligent subjects have sophisticated ideas about subjective probability, or did they have the usual ideas but prefer to use the alternative, systematic, approach? In order to throw light on this question the results of my subjective probability study[3] were re-examined from the point of view of intelligence. This showed that intelligence and subjective probability were not related. It would seem, then, that intelligence determined not the hunches the man had, but whether he chose to be guided by them.

Constant Temperature Water-Bath

A STATIONARY manometric respirometer for the simultaneous measurement of oxygen consumption and contraction amplitude of electrically stimulated muscle preparations has been developed[1]. It is necessary to immerse this apparatus in a water-bath having a temperature control of ±0·01° C.

The most compact and efficient unit available ('Circotherm' unit with mercury contact thermometer No. 4110, 25–50° C. in 1/20th divisions. Shandon Scientific Co., Ltd., London), comprising heater, stirrer, thermometer and thermostatic control is found to give an accuracy of only ±0·023° C. under our experimental conditions. However, by including a 'Variac' continuously adjustable auto-transformer (Type *V6 HMT*. Zenith Electric Co., Ltd., London) in the above heater circuit the desired temperature control is easily obtained.

An unlagged 'Perspex' bath (0·32 m. × 0·25 m. × 0·25 m.) containing 20 l. of water is used: this stands on a metal frame in the laboratory at normal room temperature. By reducing the heater input voltage from 250 V. to 75 V. the temperature fluctuations are reduced from ±0·024° to ±0·001° C. in the centre of the bath (Fig. 1) and from ±0·016° to ±0·002° C. in the corner of the bath (Fig. 2). With 75 V. the absolute temperature differences between any two positions in the bath are ±0·006° C. (reducible by the use of lagging and additional stirring devices).

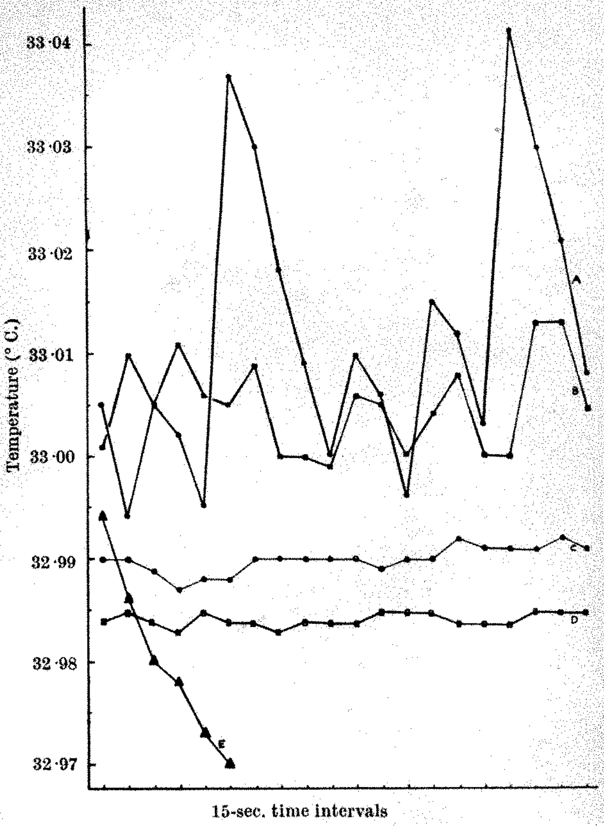

Fig. 1. Temperature fluctuations at centre of bath. *A*, 250 V.; *B*, 150 V.; *C*, 100 V.; *D*, 75 V.; *E*, 50 V.

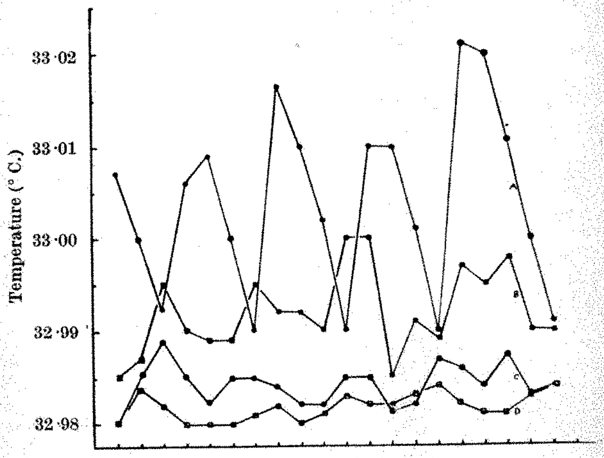

Fig. 2. Temperature fluctuations at corner of bath. *A*, 250 V.; *B*, 150 V.; *C*, 100 V.; *D*, 75 V.

In practice the water-bath is brought to the required temperature with the 'Variac' giving full mains voltage. The voltage is then reduced to the working value of 75 V. The rate of stirring is unaffected. This system avoids the necessity for using both a booster heater and a smaller one.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, February 3

Institution of Post Office Electrical Engineers (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 5 p.m.—Mr. R. H. Franklin and Mr. M. B. Williams: "Recent Developments in Line Transmission Systems".

Society of Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. Robert Clark: Presidential Address.

Society of Chemical Industry, London Section (joint meeting with the Microbiological Group, at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. J. J. H. Hastings: "Microbiological Production of Organic Chemicals".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. John Ward Perkins: "The Ancient Landscape of Southern Etruria".

Tuesday, February 4

Society of Chemical Industry, Agriculture Group (at 14 Belgrave Square, London, S.W.1), at 10.30 a.m.—Nitrogen Meeting.

Institution of Chemical Engineers (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Scientific Papers.

Institution of Civil Engineers (at Great George Street, London, S.W.1), at 5.30 p.m.—Mr. N. E. V. Viner-Brady and Mr. H. M. Pearson: "The Use of Aerial Photography by Railways".

Institution of Electrical Engineers, Measurement and Control Section (in conjunction with the British Nuclear Energy Conference, at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. J. H. Bowen and Mr. E. F. O. Masters: "Temperature Transients in Gas-Cooled Thermal Nuclear Reactors"; Mr. W. Abson, Mr. P. G. Salmon and Mr. S. Pyrah: "Boron-Trifluoride Proportional Counters" and "The Design, Performance and Use of Fission Counters"; Dr. J. Howlett: "The Application of Digital Computers to Nuclear-Reactor Design".

Royal Institution (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Prof. J. Z. Young, F.R.S.: "The Living Body as a Machine". (Further lectures on February 5, 11 and 12. Lectures for Sixth Form Boys and Girls from Schools in London and the Home Counties.)

Society of Dyers and Colourists, London Section (joint meeting with the London Section of the Textile Institute, at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Dr. T. Vickerstaff: "Progress in Textiles. A review of developments and their effect on industry and user: Dyeing and Finishing".

Wednesday, February 5

Royal Society (at Burlington House, Piccadilly, London, W.1), at 3 p.m.—Discussion on "Experimental Results with the Zeta Apparatus on Controlled Thermonuclear Reactions" opened by Sir John Cockcroft, F.R.S.

Royal Society of Medicine, History of Medicine Section (at 1 Wimpole Street, London, W.1), at 5.15 p.m.—Sir Weldon Dalrymple-Champneys: "Preventive and Curative Medicine in Ancient Peru" (Presidential Address).

Institute of Petroleum (at 61 New Cavendish Street, London, W.1), at 5.30 p.m.—Dr. P. J. V. Agius and Mr. D. Mulvey: "Mechanism of Sludge Suspension in Engine Oil".

Royal Society of Medicine, Experimental Medicine and Therapeutics Section (at 1 Wimpole Street, London, W.1), at 5.30 p.m.—Symposium on "Hæmoglobin". Speakers: Prof. C. Rimington, Dr. A. C. Allison, Dr. H. V. Ingram and Dr. J. Walters.

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 6.30 p.m.—Dr. W. J. G. Beynon: "Radio Investigations during the I.G.Y.".

Thursday, February 6

Royal Society (at Burlington House, Piccadilly, London, W.1) at 4.30 p.m.—Mr. S. A. Kitchener and Mr. R. F. Strickland-Constable: "Growth and Evaporation of Crystals from the Vapour Phase"; Mr. R. Hide: "An Experimental Study of Thermal Convection in a Rotating Liquid".

University of London (at the Middlesex Hospital Medical School, Mortimer Street, London, W.1), at 5 p.m.—Prof. T. S. Westoll, F.R.S.: "Pattern and Form in the Vertebrate Skull: a Study in Plastic Deformation and Its Limits".*

Bedford College (at Regent's Park, London, N.W.1), at 5.15 p.m.—Prof. J. Z. Young, F.R.S.: "The Brain and Its Connections".*

Institute of Refrigeration (at the Junior Institution of Engineers, Pepys House, 14 Rochester Row, Westminster, London, S.W.1), at 5.30 p.m.—Dr. Audrey U. Smith: "The Preservation of Living Cells and Tissues at Low Temperatures".

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. H. W. Melville, F.R.S.: "High Polymers" (Forty-ninth Kelvin Lecture).

University College, London (in the Anatomy Theatre, Gower Street, London, W.C.1), at 5.30 p.m.—Mr. Colin Clark: "World Population".* (First of the Newmarch Lectures in Economic Statistics. Further Lectures on February 13, 20 and 27.)

Institute of Metals, London Local Section (at 17 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. B. R. T. Frost: "Corrosion by Liquid Metals".

Royal Institute of Chemistry, London Section (joint meeting with the Kingston Technical College Chemical Society, at Kingston Technical College, Fassett Road, Kingston), at 7 p.m.—Prof. H. J. Eméleus, F.R.S.: "The Boron Hydrides and their Potential Uses".

Friday, February 7

Society of Chemical Industry, Road and Building Materials Group (joint meeting with the Institution of Highway Engineers, at the Institution of Structural Engineers, 11 Upper Belgrave Street, London, S.W.1), at 5.30 p.m.—Dr. E. K. Woodford, Mr. R. C. B. Gardner and Mrs. M. W. Spitta: "Planting and Control of Road Verges".

Society of Dyers and Colourists, London Section (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Mr. C. C. Wilcock: "Spun-dyed Fibres, their Properties and Uses".

Society for Analytical Chemistry, Microchemistry Group (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 6.15 p.m.—Annual General Meeting, 6.30 p.m.—Ordinary Meeting of the Society organized by the Microchemistry Group.

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Mr. John Marco Allegro: "The Dead Sea Scrolls".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Analyst (with a B.Sc. degree, preferably with honours in organic chemistry, and an interest in biochemistry and animal nutrition research) in the Nutrition Research Laboratory, Department of Agriculture, Glenfield, N.S.W., Australia, for duties which include the supervision and testing of analytical procedures in biological chemistry (vitamin A blood ketone assays, etc.) involving techniques such as paper chromatography and spectrophotometry—The Agent-General for New South Wales, 56 Strand, London, W.C.2 (February 12).

Reader in Chemical Engineering; Reader in Electrical Engineering (Heavy Current); Reader in Mechanical Engineering; Reader in Physical Metallurgy, Reader in Industrial Metallurgy; Reader in Mathematics or Mathematical Physics—The Registrar, College of Technology, Suffolk Street, Birmingham 1 (February 12).

Research Student (with a good honours degree in engineering or science) in Biomechanics—The Registrar, King's College, Strand, London, W.C.2 (February 14).

Assistant Lecturer in Genetics—The Registrar, The University, Sheffield (February 15).

Assistant Lecturer (with an honours degree in psychology and additional training or experience in clinical psychology) in Clinical Psychology in the Department of Psychiatry of the Faculty of Medicine—The Registrar, The University, Manchester (February 15).

International Paints Research Fellow (preferably with at least two years postgraduate research experience) at the Plymouth Laboratory, to continue biological and chemical research already in progress, including research with radioactive substances, with a view to furthering knowledge of the effect of toxic substances on marine animals and plants—The Secretary, Marine Biological Association, The Laboratory, Citadel Hill, Plymouth, Devon (February 15).

Technician (preferably with experience in workshop practice or histological techniques) at the Marine Biology Station—The Registrar, University College of North Wales, Bangor, North Wales (February 15).

Assistant Lecturer (with qualifications in either pure or applied mathematics) in Mathematics—The Registrar, The University, Manchester 13 (February 17).

Principal Lecturer (with high qualifications in physiology and preferably some experience as a university lecturer) in Anatomy and Physiology—The Principal, Loughborough Training College, Loughborough (February 21).

Senior Lecturer in Zoology at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 21).

Assistant Lecturer or Lecturer in Geology—The Secretary, The University, Exeter (February 22).

Research Fellows (Ph.D., with a special aptitude for research in high or low energy nuclear physics) in Experimental or Theoretical Nuclear Physics—The Registrar, The University, Liverpool (February 22).

Lecturer or Assistant Lecturer (honours graduate, preferably with research interests in mycology and plant pathology) in Botany at the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (February 25).

Lecturer in Biochemistry at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, February 28).

Professor of Pure Mathematics in the Durham Division of the University—The Registrar, University Office, 46 North Bailey, Durham (March 1).

Head (with an honours or higher degree in science with extensive experience of teaching, advisory work and research in agriculture and dairy bacteriology) of the College Department of Bacteriology—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (March 15).

Research Assistants (2) (theoretical physicists with research experience) in the Department of Theoretical Physics, for special research into fundamental particle and nuclear physics—The Registrar, The University, Liverpool (March 15).

Imperial Chemical Industries Research Fellows in Biochemistry, Chemistry, Chemotherapy, Engineering, Metallurgy, Pharmacology and Physics—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 30).

Turner and Newall Research Fellow in Engineering, Inorganic Chemistry or Physics—The Academic Registrar, University of London, Senate House, London, W.C.1 (April 30).

Analyst (with a university degree in chemistry or equivalent qualification in analytical chemistry, for example, A.R.I.C., with two years research experience in pure or applied chemistry) in the Department of Agriculture, Federation of Nigeria, to carry out analysis and testing of soils and plant materials in connexion with the research programme of a soils and crop nutrition team, and to supervise the routine work in the chemistry laboratory—The Director of Recruitment, Colonial Office, London, S.W.1, quoting Ref. BCD. 63/14/037.

Hospital Biochemist, Basic grade (with a B.Sc. degree, with chemistry or biochemistry as main subject or equivalent qualification)—The Chief Pathologist, West Middlesex Hospital, Isleworth, Mddx.

Laboratory Technician (preferably with experience in photography or vacuum techniques) in the Department of Physics, Washington Singer Laboratories, for duties which will include the care and maintenance of laboratories—The Secretary, The University, Exeter.

Lecturer, Assistant Professor, Postdoctorate Fellow, and a Research Assistant in the Department of Physics—Head of the Department of Physics, University of British Columbia, Vancouver, B.C., Canada.

Lecturer (Grade IIa) in each of the following Departments: Mechanical Engineering Department, Physics Department and the Chemistry Department—The Principal, Paisley Technical College, George Street, Paisley.

Physical Chemist, Scientific or Senior Scientific Officer grade (with postgraduate research experience in reaction kinetics, particularly oxidation work), at the Wantage Radiation Laboratory, to work on the development of industrially important reactions initiated by radiation—The Recruitment Officer (1018.Z/34), Atomic Energy Research Establishment, Harwell, Didcot, Berks.

Research Officer (with a university degree in forestry or a university degree in botany and a diploma in forestry) in the Department of Forest Research, Federation of Nigeria, to carry out silvicultural investigations, chiefly in the high forest regions of the Federation, but with a possibility of work in the savannah regions also—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.61/14/06.

Research Student in Physics in the field of microwave spectroscopy of solids, particularly at low temperatures—The Registrar, The University, Nottingham.

Scientific Officers (with a first- or second-class honours degree in an appropriate subject or equivalent) with the Ministry of Supply at research and development establishments, mainly in the south of England, for work in physics, electronics, electrical, mechanical or aeronautical engineering, applied mathematics, metallurgy or chemistry—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.8/8A.

Senior Geologist (with a degree in geology and not less than ten years experience in geology, including water geology and drilling) in the Water Development Department, Government of Cyprus, to take charge of the drilling section of the Department, which includes geology, and to carry out miscellaneous geophysical and other research work, and to work in close collaboration with the Hydrological Section of the Water Development Department—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.140/17/06/T.

Senior Physicist to take mainly sixth form work including university scholarship level; and a Physicist to teach throughout the school to the advanced level standard if necessary—The Warden, Trinity College, Glenalmond, Perthshire.

Senior Scientific Officer or Scientific Officer (Thermodynamics) (with a first- or second-class honours degree and a knowledge of current and future developments in aircraft and missile propulsion systems) with the Air Ministry, for work concerned with deducing performance characteristics of propulsion systems of the world's latest types of aircraft and missiles, and involves personal liaison with Fighting Services Experimental Establishments and firms in the U.K. and the United States—The Ministry of Labour and National Service, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.21/8A.

Senior Technologist (with a university honours degree in science, applied science or chemical engineering, together with some postgraduate research experience) with the Bread Research Institute of Australia, to initiate and expand investigations into the physical properties associated with the mechanical manipulation of dough, the high and low temperature storage of bread, temperature and humidity factors in oven performance—The Director, Bread Research Institute of Australia, 111 Pacific Highway, North Sydney, N.S.W., Australia.

Specialist Officer (Statistician) (with a good honours degree in mathematics and two years postgraduate experience in statistics as applied to agricultural research) with the Federation of Nigeria, for duties which will include the building up and supervising of a statistics branch in the Department of Agricultural Research—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/14/048.

METALLURGISTS REQUIRED IN THE Shepherd's Bush Laboratories of British Insulated Callender's Cables Limited for research and technical service duties on a wide variety of problems dealing with both ferrous and non-ferrous metals of interest in the manufacture of electric cables, allied equipment and transmission structures. Opportunities are available for gaining experience of industrial processes. Applicants should be well qualified and preferably have had some previous experience. Five-day week. Pension fund.—Applications, giving details of age, qualifications, and experience, should be made to Personnel Officer, 38 Wood Lane, London, W.12.

TRADE ANNOUNCEMENTS

THE PRICE OF SAFETY IS THE COST OF a JENCONS interchangeable desiccator.—Send for price and spares list to Jencons (Scientific) Ltd., Mark Road, Hemel Hempstead, Herts.

GRANTS & SCHOLARSHIPS

UNIVERSITY COLLEGE OF NORTH STAFFORDSHIRE

U.S. RUBBER CO. POSTGRADUATE RESEARCH STUDENTSHIP

Applicants for this Studentship should have a good honours degree including chemistry. The successful applicant will be expected to read for a higher degree, working on cationic polymerization under the direction of Dr. P. H. Plesch. Stipend not less than £400 per annum.

Applications, giving a brief curriculum vitae and names of two referees, should reach the Registrar, The College, Keele, Staffs, by February 22, 1958.

SCHOLARSHIPS ABROAD 1958–59

Applications are invited from British students for scholarships offered by Austria, Belgium, Brazil, Denmark, Finland, France, Germany, Iceland, Iran, Italy, Japan, The Netherlands, Norway, Poland, Portugal, Spain, Sweden, Switzerland, and Yugoslavia. The awards are mainly for university graduates and undergraduates and are tenable for periods varying from a few weeks to twelve months during the academic year 1958-59.

Full particulars and application forms, for which a stamped (3d.) self-addressed adhesive label should be sent, are obtainable from the British Council, 65 Davies Street, London, W.1, or from any British Council office in the United Kingdom.

UNIVERSITY OF NOTTINGHAM

DEPARTMENT OF PHYSICS

Applications are invited for a Research Studentship in Physics in the field of microwave spectroscopy of solids, particularly at low temperatures. Value £350 per annum, plus fees.

Further information and form of application may be obtained from the Registrar.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY

Applications invited from honours graduates in chemistry or physics for immediately available bursaries of about £400 per annum to carry out fundamental research on combustion and flame propagation, normally leading to Ph.D.

Applications, with curriculum vitae, to Dr. J. H. Burgoyne, Department of Chemical Engineering, Imperial College, S.W.7.

GRADUATE RESEARCH SCHOLARSHIPS

DEPARTMENT OF BIOLOGY, McMASTER UNIVERSITY

Applications for Graduate Research Scholarships are invited from qualified students wishing to work towards the M.Sc. and Ph.D. degrees. The minimum annual stipend for a twelve-month period is $1,500. Research in progress: Ecology and physiology of aquatic and bloodsucking insects; population dynamics of grasshoppers (D. M. Davies). Formation of lake bottom sediments; sensory physiology in fish (H. Kleerekoper). Viruses in wild plants; cytological studies (W. D. MacClement). Physiology of yeast sporulation; ecology of soil microflora (J. J. Miller). Experimental embryogeny; organic terrain organization; palaeobotany and evelopmental morphology; applied palaeobotany and palynology (N. W. Radforth).

Applications should be sent before March 15, 1958, accompanied by university transcript and letters of recommendation from two professors, to Dr. H. Kleerekoper, Chairman, Department of Biology, Hamilton College, McMaster University, Hamilton, Ontario, Canada.

ROYAL HOLLOWAY COLLEGE

UNIVERSITY OF LONDON

A Tutorial Research Studentship in Mathematics (Pure or Applied) is offered for the session 1958-59, renewable for a second year. The Studentship is intended to enable the holder, while gaining some experience of university teaching, to work for a higher degree of the University of London or some other university. Value £350 a year, or £170 with board and residence.

Particulars may be obtained from the Principal, Royal Holloway College, Englefield Green, Surrey, to whom applications should be sent not later than March 1, 1958.

NUFFIELD FOUNDATION

BIOLOGICAL SCHOLARSHIPS AND BURSARIES

The Nuffield Foundation, as part of its programme for the advancement of biological studies, is prepared to offer for the academic year 1958-9 a limited number of Scholarships and Bursaries to enable persons who have graduated in physics, chemistry, mathematics or engineering, but who have had no training in a biological subject, to receive such training in biology as will enable them in due course to undertake research and teaching in the United Kingdom in the biological sciences. The Scholarships, which are senior awards, are intended for persons who have already undertaken some postgraduate research in their own subject. The Bursaries are intended to enable those who have recently graduated to complete a course of training in biological subjects including, if considered necessary, a full honours degree course in biology. In the case of both scholars and bursars the Foundation will pay the cost of university and/or college fees in addition to a maintenance award. Graduates of Universities in the United Kingdom, of either sex and preferably between the ages of 22 and 35, are eligible to apply.

Applications for awards in 1958 must be received before April 1, 1958, by the Director, The Nuffield Foundation, Nuffield Lodge, Regent's Park, London, N.W.1, from whom full particulars and application forms can be obtained.

L. FARRER-BROWN,
Director of the Nuffield Foundation.

NUFFIELD FOUNDATION

SOCIOLOGICAL SCHOLARSHIPS AND BURSARIES

The Nuffield Foundation, in pursuance of its programme for the advancement of sociological studies, is prepared to offer for the academic year 1958-9 a small number of Scholarships and Bursaries to enable graduates in academic subjects other than the social sciences, psychology or economics, to study the social sciences. The Foundation's particular object is to enable men or women, who are already well qualified in other disciplines, particularly the natural sciences or humanities, to receive a training in, for example, political science, social psychology, anthropology, socal statistics and sociology generally (but not economics) so that in due course they may undertake research or teaching in the United Kingdom in these subjects. The Scholarships, which are the senior awards, are intended for persons who have already undertaken some postgraduate work in their own subject. The Bursaries are intended to enable those who have recently graduated to take a course of training in sociological subjects. In the case of both scholars and bursars the Foundation will pay the cost of university and/or college fees in addition to a maintenance award. Graduates of Universities in the United Kingdom, of either sex and preferably between the ages of 22 and 35, are eligible to apply.

Applications for awards in 1958 must be received before May 1, 1958, by the Director, The Nuffield Foundation, Nuffield Lodge, Regent's Park, London, N.W.1, from whom full particulars and application forms can be obtained.

L. FARRER-BROWN,
Director of the Nuffield Foundation.

RESEARCH SCHOLARSHIPS AT THE INSTITUTE OF CANCER RESEARCH: The Royal Marsden Hospital invites applications from graduates with special interest in the chemistry and biochemistry of the nucleic acids. The work will be carried out under the supervision of Dr. K. S. Kirby, and the successful candidate will be encouraged to proceed to a higher degree.—The post is tenable at the Pollards Wood Research Station of the Institute of Cancer Research, Royal Cancer Hospital, Nightingales Lane, Chalfont St. Giles, Bucks, and applications should be sent direct to Dr. Kirby at this address not later than February 28, 1958.

MISCELLANEOUS

A MAJOR OIL COMPANY IS MAKING a survey of "Automatic Process Stream Analyser" instruments available from sterling sources. This is meant to include only robust apparatus suitable for outdoor mounting to provide a continuous monitoring of petroleum processes by an analytical method as distinct from the conventional environmental methods.

The information will be shared with the Company's world-wide associates in both the sterling and dollar areas.

To ensure there are no major omissions it is requested that manufacturers of such instruments, including major suppliers, submit an outline list of their products in this field. Every reply will be acknowledged.

Reply to Box 607, T. G. Scott and Son, Ltd., 1 Clement's Inn, London, W.C.2.

Firm in the Midlands has spare extraction refining and drying capacity available. Suitable for extraction of vegetable and animal oils, vegetable pigments, vitamin extracts, and work of a similar nature. Would consider processing for customers or would purchase suitable raw materials.—Box 602, T. G. Scott and Son, Ltd., 1 Clement's Inn, London, W.C.2.

ARTIFICIAL EARTH SATELLITE, 1958 ALPHA

ON October 4, 1957, the launching of the first artificial Earth satellite, 1957 Alpha, was announced (*Nature*, October 12, 1957); and this was closely followed by the news that the second artificial Earth satellite, 1957 Beta, had been launched on November 3, 1957 (*Nature*, November 7, 1957). Both these *Sputniks*, as they were then called, were successfully launched, presumably from Russian territory.

Now comes a third announcement to the effect that the third artificial Earth satellite, Alpha 1958, at present known as *Explorer*, was successfully launched from Cape Canaveral, Florida, on January 31.

1958 Alpha is apparently travelling on a larger orbit than that of either 1957 Alpha or 1957 Beta, for it is taking twenty minutes longer to encircle the Earth than the 1957 satellites. The reported minimum height is about 200 miles and the maximum about 1,700 miles. Its mass is about 18 lb., and that of the final stage of the rocket, after burning out, is estimated to be 12·67 lb. Both have been designed to travel along the orbit as one unit.

Because 1958 Alpha, having a total mass of about 29·7 lb., is small compared with 1957 Alpha and Beta (184 and 1,118 lb., respectively) the instruments which it carries are also miniature, but they will probably yield results as valuable as the larger ones. The new satellite is a 6-in. tube about 80 in. long. Apart from radio transmitters, it carries instruments for measuring temperatures, cosmic rays and the effect of space dust on its outer surface.

Once again, therefore, it is *Nature's* pleasant task to convey to the scientists concerned the congratulations of all their colleagues throughout the world. Science and technology are advancing in great strides, though clearly the launching of these three satellites, like the control of thermonuclear fusion, are just the beginnings of developments in space technology on one hand and atomic technology on the other with all their scientific and technological complications. Yet now is the time to draw morals and learn lessons from these achievements which, without doubt in the none-too-distant future, will exert profound impacts on man and his civilization.

During the past few months, three great achievements in science and technology have justifiably received world acclaim: (1) the launching of artificial Earth satellites by scientists in the U.S.S.R.; (2) the development and control of thermonuclear fusion by scientists in Great Britain and the United States; (3) the launching of an artificial Earth satellite by scientists in the United States. We have used the expression 'by scientists in' deliberately, for the implications and interpretations already attached to these great scientific achievements, especially by the more sensational or politically biased newspaper Press, may do much harm to scientific reputation. It is therefore important to recognize that not one of these great achievements can be looked upon as wholly Russian or American or British. There is every reason for believing that the great work which led to the launching of the satellites in the U.S.S.R. was carried out by teams which comprised some scientists of Western birth and/or training. Among those who have brought about the control of thermonuclear fusion in the United States is one of British birth and training, whereas among those in Great Britain are an Australian and a Canadian. Germans are outstanding among the scientists who were responsible for the successful launching of the satellite from American soil.

Some branches of science, especially the physical sciences, are becoming more and more the tools of diplomatic intrigue and political pressures. Certainly, scientific achievement is being thrust forward quite sensationally in the mad rush for national prestige. Yet scientific discoveries are not suddenly made by men who, by birth or consent, are entitled to claim a certain nationality; they are the results of good training, patient and sometimes long-continued work often fraught with disappointment, team-work sometimes spiced with real personal genius, and all these are based on the work of previous generations. The nationality of the scientists plays no part whatever, though we must give credit to those countries which, in their wisdom, give financial and other support to such scientists. It is therefore of the utmost importance at this stage to recognize that men born and trained in the United States, Germany, the U.S.S.R., Canada, Australia, New Zealand, Great Britain and possibly other countries have teamed up and produced these recent gratifying results; and it is about time that credit should be given to these scientists and due recognition awarded to them, instead of to the countries in which they happen to be working.

This false 'nationalism' of science can do nothing but harm in the long run, for it tends to force scientists under still stronger political control (thus gradually depriving them of that freedom under which science has always flourished best) and has already led to ill-informed interpretation and presentation, and not a little acrimony. All this is due mainly to fear of giving away secrets to a potential enemy (in spite of the fact that science moves so fast that what is a 'classified' secret to-day becomes 'unclassified' world news to-morrow); anxiety to enhance national prestige (on false premises); and the determination of politicians and Service brass-hats to keep science under their control in order to achieve their own short-sighted objectives. In this false presentation of scientific achievement, this artificial moulding of public opinion, truth (the main objective of science itself) becomes the first casualty.

It may be of interest now to reveal that, after the 1957 satellites were launched, British and American scientists willingly came forward with their observations and results for publication to the world. Some of these appeared in *Nature*; yet, in spite of long-continued efforts on the part of the Editors, nothing could be obtained from the Russians themselves, though the work was supposed to be part of the Russian contribution to the *International* Geophysical Year. In fact, the only contacts that could be made were with Soviet diplomats (and these contacts proved sterile). Two direct communications to one of the leading men of science in Moscow who was closely connected with the scientific work involved still remain unanswered. This compares unfavourably with President Eisenhower's pronouncement that results from 1958 Alpha will be given to the world, and reveals a deplorable reluctance on the part of the Russian authorities to allow their scientists to work in collaboration with scientists in other countries. This international race in science may achieve some good in that it might enhance respect for science among political and other authorities and the public; but by and large, it is not good for science, which has always flourished best in an atmosphere of freedom and collaboration. Moreover, it is bound to cause duplication of scientific effort (and nowadays scientific research can be a very expensive item in any nation's budget); this is a waste of time which must inevitably slow up world advancement of science. The fact that this is not recognized by some is indicated in one British newspaper's leading article commenting on the launching of the third Earth satellite when it asks: "Why is Britain left helpless and earthbound in this conquest of space? What are our leaders doing?", and gives the answer as "utterly shameful".

Similar reactions occurred when the results of research on the control of thermonuclear fusion were announced. It is true that the scientists working in Britain were ahead of those working in the United States, and this is now recorded in *Nature* and elsewhere. We are in no position to express any opinion on the criticisms hurled at American authorities and the accusation that they deliberately planned the holding up of announcements from Britain for the sake of their national prestige. In any event, in the long run it will not matter who was first in the field, provided, for the sake of history, credit is given to those who have earned it. But the immediate effect of such international squabbling can be very harmful and distressing. Moreover, it inspires ill-feeling and bad faith where neither is deserved; and this all too often leads on to misunderstandings, false accusations and even the deliberate masking of the truth. For example, quite unknown to the Editors at the initial stages, it was agreed among the scientists concerned (of several nationalities) and others closely connected, that the first scientific details concerning the work on thermonuclear fusion in Britain and the United States should be published in *Nature*. This was indeed a compliment to *Nature*, though it was obviously realized by those concerned that, by publishing in this journal, the news and results would quickly reach most scientists throughout the whole world.

The articles were eventually published in *Nature* of January 25; but not before there had been some severe criticism from certain sections of the newspaper Press, mainly from writers who anyhow could scarcely be expected to understand and interpret what appears in *Nature*. A further criticism came along after publication, when *The New Scientist* in its issue of January 30 suggested that the Editors of *Nature* had substantially departed from accepted practice by omitting the dates from the articles published, and implied that thus they were helping those to claim priority which was not their due. Actually, throughout its long history, *Nature* never has published dates on its main articles. All seven of the articles on thermonuclear fusion were received at *Nature* office in the normal way within a few days of each other and treated in the normal way.

All this attempted 'nationalization' of science for the achievement of political prestige, this squabbling among Press and public concerning who came first, are very childish indeed. It must be disconcerting, if not discouraging, to the scientists; and, as has been seen, is bound to lead to distortion of the truth. The stark facts are that quite a number of countries are training scientists, some of whom have proved their worth and even genius in the past few months. The fact that their proving grounds were in the United States, the U.S.S.R. and Great Britain is, fundamentally, of little consequence to science itself, for, as we pointed out in our article congratulating the scientists in Russia on their magnificent achievement last October (*Nature*, October 12), there is no such thing as Communist science or American science or British science: there is just—science, the search for the truth. It is unfortunate that though many countries are now supporting this material search for the truth, too many of them are interfering with its exposition.

The *New York Times* of February 1, in commenting on the launching of 1958 Alpha, gives a firm warning that: "This is a good time for us to remember that neither Russians nor Americans can claim any kind of exclusive credit for the progress made towards man's conquest of space. Like all man's greatest scientific adventures, the march of humanity towards the cosmos is the product of many men of many nations over many centuries. . . . To realize the possibilities now before us we shall have to show that all humanity is capable of rising to the challenge". This can only be done by looking upon the march of science as an endless, moving picture in which many characters have a part to play; where star actors can give of their best only when they are supported by a good and well-trained cast; and where, as occasion demands, praise or blame be accorded to the actors for their acting and not their place of birth.

TECHNOLOGICAL HUMANISM

THE address given by the Duke of Edinburgh in Manchester on November 22 when he opened the new extensions to the Manchester College of Science and Technology included some welcome comments, and it may be reasonably hoped that his lucid and cogent argument will bring home certain truths and facts to quarters which have long ignored them. The dependence of the welfare and security of Britain upon an adequate supply of properly trained and educated scientists and technologists could scarcely have been better put. Nor did the Duke mince his words. Lagging production, he said, is properly equated with chronic poverty, and he gave neither encouragement nor opportunity to those who advocate excessive specialization or argue that it is inherent in a scientist or technologist.

Very clearly, but firmly, the Duke of Edinburgh pointed out that a clash between science and technology and the humanities is not inevitable, and his advocacy of technology does not lead towards technocracy. He insisted that a specialist of any kind, whether in science or in the arts, is not necessarily the well-educated man that we need to produce, and that it is doubtful whether sufficient science is included in the general education of the humanist for the latter to be described as well educated to-day. Science, or any other branch of knowledge, is only an educational tool the use of which depends on the character and outlook of the individual possessing it. Furthermore, he reiterated the truth that our limited scientific and technological man-power can only be efficiently and economically used by administrators who know enough to recognize for themselves the fields of research and development likely to prove most fruitful.

Apart from thus commending the attention being given in the College to management, the Duke of Edinburgh stressed three points which apply no less to the current expansion of technological and scientific education generally than to the particular developments at Manchester. First, there is needed the whole-hearted support and co-operation of industry as a whole, with money and equipment and in terms of part-time teachers. Secondly, there is required the understanding of individual industrialists in formulating their needs for people with specific qualifications, and then in seeing that, when trained, these graduates do, in fact, obtain posts which offer full scope for their qualifications and talents. Thirdly, scientists and technologists should seek to dispel the present unreasoning prejudice against their subjects.

Apart from this last point, on which the Duke of Edinburgh laid perhaps his main stress, his address emphasized the arguments of recent addresses by Sir Eric Ashby on technological humanism and by Dr. R. P. Linstead on an education for our times. The goal should be the production of a well-educated citizen, capable of independent thought and initiative. To this end, the full co-operation of scientists and technologists both as individuals and corporately through their professional associations will still be necessary to overcome prejudices which would hinder the development of a system of education capable of providing the nation with the administrators, scientists, technologists and technicians as well as ordinary citizens, who can take full advantage of the opportunities of to-day. Even in securing the full co-operation of industry with the universities and technological and technical colleges, there are prejudices to be overcome; indeed, it is difficult to believe they are not the real reason why the Manchester College of Science and Technology has had to curtail its plans for expansion, because of a disappointingly small grant from the University Grants Committee. The position may also be due to the anomalous arrangement under which the development of higher technological education in Britain is only partly the responsibility of the University Grants Committee; but in the present financial stringency, the removal of any anomalies which hinder the wisest and most economical use of Britain's limited resources should be a principal object of Government policy.

The Manchester College of Science and Technology is seeking to meet its difficulty by an approach to local industrial firms, which it is hoped will enable it during the coming year to wipe off its existing mortgage of nearly £1·5 million, and this appeal could well result in much closer co-operation and understanding between local industry and the College. Nevertheless, the contribution which the College could make to the expansion of technological education is so considerable and unquestioned that there are strong grounds for supporting an alternative proposal that the University Grants Committee should be authorized to make a capital grant towards the discharge of the outstanding mortgage.

The sincerity of the Government's intentions in regard to the expansion of technological education are, in fact, better shown by the support it gives to the three major institutions—the Imperial College of Science and Technology, the Royal Technical College, Glasgow, and the Manchester College of Science and Technology—than by the progress of the expansion on which Mr. Geoffrey Lloyd, Minister of Education, gave a further interim report in the House of Commons on November 28. Apart from the anomaly in regard to the University Grants Committee already noted, the plea of regionalism is scarcely consistent with the development of the Salford Technical College while expansion at Manchester is frustrated, particularly in view of the proposed devolution of responsibilities for training technicians and craftsmen which is proposed at Manchester. In all these circumstances, Mr. Lloyd's statement, so warmly welcomed in the House of Commons, is disturbing rather than reassuring. Besides eighteen new technical colleges and seventy-nine major extensions of existing colleges in Britain since February 1956, plans for a further five colleges and seventeen major extensions have been approved and a further fourteen new colleges and twenty-eight major extensions are contemplated. Mr. Lloyd gave no indication as to the balance between technical and technological facilities, nor could he report on the technological developments at the universities, which, like those at the three major institutions already named, are outside his department. Indeed, as Sir David Anderson implied in his address in Dublin to Section G of the British Association, the country's requirements for technicians are scarcely known. It may be that, until the Carr Committee reports, the requirements for training craftsmen and technicians cannot be formulated with any precision, although a useful estimate could be made from the number of scientists and technologists which it is estimated that we require. It is on this basis, however, rather than on the programmes of other countries, that the expansion of technological and technical education in Britain should be considered.

It is most desirable that financial support for the expansion of the Manchester College of Science and Technology and other colleges of technology and technical colleges should be drawn from industry as well as from the Government and local authorities. That £100,000 should already have been received from local industry in response to the Manchester appeal (made in the first instance to meet the expected deficit in the current academic year) is a healthy sign. It is understood, however, that the College is likely to need £850,000 from industry during the next five years, and it is important to remember that the expansion of technological and technical education depends on co-operation from industry in other ways, some of which are even more important than direct financial assistance and may themselves be costly to industry.

This is apparent from the recently published report* of the second National Conference between Industry and the Technical Colleges arranged last May by the Federation of British Industries (see also *Nature*, **179**, 1226; 1957). Indeed, the report makes much more encouraging reading than Mr. Lloyd's statement, and it is noteworthy how far the ideas which Sir Eric Ashby, for example, had just expressed in his May Lecture to the Institute of Metals and which Dr. Linstead developed in his Hinchley Memorial Lecture in November were reflected on all sides at the Conference. There was overwhelming support for the view that the primary task is to produce well-educated men and women whether they are scientists or technologists or not, and Lord Hailsham's address at the formal opening of the Conference was far more reassuring than recent speeches of his successor as Minister of Education, Mr. Lloyd.

One point made by Lord Hailsham deserves to be widely noted. The Government would expect industrialists, he said, to play an important part on governing bodies of technical colleges, and this is the more important in view of the Government's proposals in regard to local government reform. The close co-operation between industry and technical education which is so essential can scarcely be secured unless industry itself comes to participate directly in the management of the colleges, and this came out quite as clearly in the subsequent discussions at the Conference on sandwich courses, as in Lord Hailsham's remarks. Moreover, in referring to the need for a two-way exchange of ideas between Government and industry to obtain a satisfactory solution to some problems of sandwich courses, Lord Hailsham stressed the bearing of an informed public opinion upon the financial question. Technical education, he believes, is at last capturing the imagination of the public, and if public opinion takes education seriously, there will be no difficulty about getting the money.

Another main discussion at the Conference centred around á challenging paper by Dr. P. F. R. Venables on "Liberal Technical Education: an Economic Necessity". Lord Hailsham himself insisted that a good general education is the first essential of a good technical education, and stressed the importance of a liberal element in technical education, which is the principal means of further education for most young people; he also pointed out that we have the difficult task of providing an industrial society which, by virtue of its moral structure, can lead the world to a smoother and more rational future. The divorce between the scientist and the student of the humanities must end. In an industrial age, everyone needs a general knowledge of the capabilities and characteristics of scientific investigation and mathematical discipline; but everybody, however specialized, needs also to recognize that this specialization is only part of a more general life in which the intellectual, moral, spiritual and æsthetic qualities have an essential place.

That such views should be expressed by a Minister of Education, as he then was, is in itself encouraging, and although Lord Hailsham said nothing about the importance of concentration of limited resources for the development of technological education, Sir Harry Pilkington, in his survey of technical education, at least recognized the need, and his figure of eight is a much more realistic number for the colleges of advanced technology that we can for the present expect to staff and equip adequately. Moreover, the question of quality becomes more important as we attempt to give effect to the ideas about a liberal technical education which Dr. Venables developed in his paper. Particularly during the period of transition, experiment and development into which we have entered, it is essential that adequate resources for experiment and for trial of new ideas should be assured in a few colleges rather than that available resources should be spread too widely. The most superficial development of Dr. Venables's reference to the contribution of the technical college library should indicate the immense possibilities inherent in a liberal policy to such libraries, and the way in which it could react on adult education generally and facilitate a more effective use of resources.

---

* Federation of British Industries. Report of the Second National Conference between Industry and the Technical Colleges, 15 May, 1957. Pp. vi+71. (London: Federation of British Industries, 1957.) 5s.

Dr. Venables argued convincingly that a utilitarian philosophy is an insufficient basis for human beliefs and sympathies, for æsthetic experience, for human action and as a bond for society, and that it is therefore quite inadequate as a basis for education, knowing little of virtue and perhaps even less of creative imagination. It is probably the main factor responsible for starving the technical college libraries —and probably also those of universities and other libraries. But that is only one of the reasons why utilitarianism is a major danger against which we must guard in attempting to develop a broadly based education adequate for our times. The three main characteristics of a liberal technical education stressed by Dr. Venables—diversity of experience confronting the student, of subjects to be studied, disciplines to be mastered, and methods to be used; intensity of illumination of the student's mind and experience; and proper timing of the phases of education in relation to the student's personal development—all demand staff of high quality and open-mindedness, and conditions in which students have the opportunity to enrich their lives and develop their personalities.

All this bears, too, on the difficult questions of the selection of students and the amount and conditions of student grants, though not always in the way that the sponsors of the National Union of Students' recent survey of student expenditure might expect. Dr. Venables points out that the basic scientific subjects should be taken mainly in the earlier part of a professional course, though not to the exclusion of technological subjects, and that is a prime reason for liberal treatment of technological subjects. Moreover, if a diversity of appropriate teaching methods is to have its full effect, we must be concerned to see that the system of selection of students and awards does not in itself discourage the student from thinking and reflecting on his work, or hinder the strengthening of his powers of thought or the deepening of his penetration so essential either in mastery of a specialism or fostering a liberal education.

What is encouraging in Dr. Venables's paper and its reception by the Conference is the challenge to thought and the acceptance of that challenge by the Conference. It was recognized that full-time and sandwich courses provide the opportunity for experiment, and his assertion that we have relied too long and too much on part-time education was unchallenged. Sir Norman Kipping, in his summing up, showed as clearly as Sir Harry Pilkington the extent to which industry is prepared to co-operate and to work out the most effective means of co-operation. Moreover, he welcomed the Minister's stress on the promotion of education as distinct from its administration, and the address of Mr. A. A. Part, Under-Secretary of the Ministry of Education, showed that the permanent officials at the Ministry were just as alive to the real issues.

With such an enlightened attitude on the part of the Government and its officials, with increasing readiness on the part of industry to co-operate and to follow the lead of Sir Harry Pilkington, Sir Alexander Fleck, Lord Weeks, Lord Hives and others, and with educationists like Dr. Venables, Sir Eric Ashby and Dr. Linstead pointing the way, it may well be asked wherein the danger lies that the present plans may be ineffective or not realized. Despite the unsatisfactory character of the administrative arrangements, the University Grants Committee cannot fairly be blamed for deficiencies in the technological education of Britain. Lord Simon of Wythenshawe, in a valedictory address to the Court of Governors of the University of Manchester, recently remarked that the generosity of Government grants to universities is not always appreciated, and added that in a letter regarding the next quinquennium the Committee had emphasized the need to strengthen teaching rather than research and especially the teaching of technology.

It is true that, as regards the question of general education, the universities themselves could do something more to help the schools to make the necessary adjustments, and that there is room for better co-operation and clearer understanding at this level, though Dr. Linstead emphasized the delicate and sympathetic handling which these borderland problems require. The Duke of Edinburgh's speech, however, and the difficulties of the Manchester College of Science and Technology, point to the real need. First, there is the need for wider public understanding of what is required and what is at stake, and a deeper appreciation of the place and worth of technician, technologist and scientist alike. That is an essential condition for the creation of an informed public opinion that will ensure an adequate financial provision for education at all levels, from the Treasury or from local government sources, and also a continuing supply of students for technical and technological as well as scientific courses. This itself is in part a problem of adult education, but such an enlightened public opinion provides the ultimate means of overcoming the political, sectional and local prejudices which hinder the rational planning of resources and the elaboration of a national, regional and local system of education.

INFLUENCE OF WAR ON THE PRODUCTION AND USE OF FERTILIZERS

The World Fertilizer Economy

By Mirko Lamer. (Studies on Food, Agriculture, and World War II.) Pp. xvi+715. (Stanford, Calif.: Stanford University Press; London: Oxford University Press, 1957.) £5 net.

THE agricultural output of the United Kingdom increased greatly during the Second World War, mainly due to a large increase in the acreage under tillage crops. This change in farming resulted in a near-revolution in many of the techniques used; outstanding examples were marked increases in mechanization and in the use of fertilizers. The

Colle

War stimulated progress in many other countries, but in some others the use of fertilizers was seriously curtailed by war-time damage to plants or by restricted supplies. The main purpose of Dr. Lamer's book is to state and to discuss the changes in production and consumption of fertilizers which occurred during the war period in all the important fertilizer-using countries. Reviews of the fertilizer position in the pre-war and post-war period have already appeared for a few countries, but this book provides the first account on a world-wide basis of the industrial, agricultural, social and economic factors which were involved.

The first few chapters set the stage by giving general accounts of fertilizer history, the forms in which fertilizers are prepared, their role in plant nutrition, and their values for crops. Yield responses in relation to profit are discussed with special reference to the mathematical equations which have been derived for fertilizer response curves. There is little in this section of the book which has not been published previously.

In succeeding chapters fertilizer production and consumption are dealt with exhaustively, country by country; features of pre-war trade in fertilizers are discussed in relation to the changes imposed by the War and to the re-establishment of trade afterwards. An interesting section is devoted to the trade agreements which existed before the War between the producers of fertilizers in individual countries, and also in different countries. Most of the old cartels were broken up during the War, and the author discusses the possible establishment of trade agreements in the future. Changes in the forms in which fertilizers are produced, due to the development of new processes and to the exploitation of new raw materials, are described.

The patterns of fertilizer production and use in Allied and Axis countries are compared, and the effects on fertilizer use in neutral and non-belligerent countries are stated. Special attention is given to the arrangements made by the United States, the United Kingdom and Canada to promote co-operation in fertilizer production and trade for the benefit of all the Allies. Most countries controlled the sale and use of the fertilizer supplies that were available; the methods used for achieving this are stated and estimates are made of their success.

Two chapters are devoted to the use of fertilizers in the Soviet Union; they are particularly valuable since it is difficult to obtain any reliable information on fertilizer production and consumption in the U.S.S.R. Full documentation is given and the maximum use has been made of information from both official and unofficial sources. In 1913, Russia's fertilizer industry was practically non-existent—only a few hundred thousand tons were used and most was imported from Germany. Domestic fertilizer production rose from 180,000 tons (of products) in 1928 to 3·7 million tons in 1938. The War reduced output and the 1938 level was not again attained until 1948. Production in the U.S.S.R. in 1955 was estimated as 9·6 million tons of products of all types.

The book is concluded by a brief assessment of the future of fertilizer use in relation to economic, industrial, and agricultural factors. The author concludes that "in all countries of the world, fertilizers are one of the most important strategic weapons of modern agriculture"; he considers that: "Increasing food production by increasing the use of fertilizers seems often to be a better road to agricultural and national welfare in under-developed countries than building electric power plants, roads, and machine industries, and relying on gifts of food from well-to-do countries".

Full statistics for production, consumption and foreign trade are given and there is very adequate documentation throughout the book. The amounts of information available for different countries have, inevitably, varied and the account given is therefore fragmentary in places, and there are many gaps. A criticism is that related subjects are often widely separated in the text. It would have been easier for a reader to have had all information on the British Commonwealth or the U.S.S.R. in adjoining chapters; the layout adopted separates information on any one country or group of countries by a number of chapters dealing with other subjects. In spite of this the book is of very real value and interest, and is recommended to all who are concerned with the wider aspects of the manufacture, supply and use of fertilizers.

G. W. COOKE

SIR ERNEST SHACKLETON

Shackleton

By Margery and James Fisher. Pp. xvi+559+46 plates. (London: James Barrie Books, Ltd., 1957.) 30*s*. net.

DURING the years between the two World Wars, polar exploration in its heroic age held the palm for adventure; and many a schoolboy's hero was Sir Ernest Shackleton. I still remember the thrill when, not many years after his death, I found "The Heart of the Antarctic" in my preparatory school library and how I trudged every mile with him (by torchlight, under the pillow), when he got so near to, and yet turned back so far from, the Pole.

I next turned to "South", the account of his *Endurance* expedition, which, appropriately enough, must surely rank as one of the most extraordinary feats of human endurance of all time. More than forty years before Dr. Fuchs, Shackleton had conceived the idea of crossing the Antarctic continent from the Weddell Sea to the Ross Sea. Unfortunately, ice conditions that year were exceptionally severe and his ship became trapped in the pack at the base of the Weddell Sea just short of his landfall. How the expedition drifted north in increasing pressure until the ship was crushed like match-boarding before their eyes; how, after sledging across disintegrating pack-ice and then taking to the boats, the whole expedition landed safely on Elephant Island; how Sir Ernest himself, with five companions, sailed in an open ship's lifeboat across 800 miles of the world's stormiest ocean to South Georgia and crossed that completely unmapped island in search of help and how ultimately the entire party was saved without loss of life must surely remain an epic in leadership at its best.

Behind the explorer lay the man, and the demands of an expedition brought out all that was best in him—the fantastic physique, which enabled him to man-haul sledges for weeks on end in sub-zero temperatures on a twenty-ounce diet; the judgment which persuaded him to turn back when only a few marches from the South Pole; the improvizing genius which helped him to bring back his crew of the *Endurance*; the strong sense of the romantic without which no great deed is accomplished.

Back at home in settled life these gifts did not serve him so well, and whether it was mining concessions in Hungary, shares in a cigarette company or taxi business, or wild-cat schemes to search for hidden treasure, it was obvious that there was bound to be one outcome—yet another expedition to the Antarctic. To him, fulfilment could only come through polar exploration, and the tragedy too often occurring in such cases of an ageing man becoming more and more of a misfit in civilization, yet less and less capable of following his bent, was averted in Shackleton's case by his early death.

All these facts of a complex character and a detailed description of the four polar expeditions in which he took part, the last three as leader, are fully and, indeed, admirably set out in this definitive life, which is both timely and well written. Just as Wolsey and Roberts never disliked each other (indeed, they scarcely met, the rivalry was created by their respective staffs) so I think it is extraordinarily unlikely that Shackleton and Scott were so antagonistic as some of their more ardent supporters would have us believe. The evidence is examined scrupulously, and neither figure emerges with discredit.

The only fault of this book lies in its almost too-detailed approach. If ever there was a life of heroic achievement calculated to bring tears to the eyes, then surely it was Shackleton's. Yet it is not until his death in South Georgia, back again in his old haunts, chasing the rainbow with the same zest as twenty years before, that this tale ever becomes really moving, though through every one of the 559 pages there emerges one who was truly a man among men.

SUPPLY AND QUALITY OF CRAFTSMEN

Recruitment of Skilled Trades

By Prof. Lady Gertrude Williams. (International Library of Sociology and Social Reconstruction.) Pp. vii+216. (London: Routledge and Kegan Paul, Ltd.; New York: Humanities Press, 1957.) 23*s*. net.

CONCERNED with the continuing shortage of skilled workers in industry, Lady Williams has made an inquiry to determine the reasons for the deficiency. Since most skilled workers are to be found in engineering, ship-building, the motor-repair industry, printing and building, the inquiry was confined to these industries and, since the number of skilled women workers is extremely small, it dealt only with male apprentices. Questionnaires were sent to some 9,000 firms and 550 of them replied; personal interviews were carried out in some of them. Making no claim for the statistical accuracy and significance of the inquiry, Lady Williams has still been able to substantiate her findings from many talks with individuals of wide experience in industry. All who are familiar with recruitment and training in industry and who love their country would like to deny the depressing story she tells; what she writes is all too true.

In the renowned engineering industry of Great Britain, for example, there are comparatively few firms with well-established training schemes for craftsmen run by competent people; the number of well-equipped training centres where teaching is the prime concern can be counted on the fingers of four hands. Where training is systematically carried out it is in the large firms which bear the responsibility of training not only enough skilled men for themselves but also for a very large number of small firms; many firms, including electrical firms employing thousands of workers, employ no apprentices at all. In the building industry the position is worse than in engineering, although Lady Williams concedes that the nature of the industry makes it extremely difficult to organize effective apprentice schemes. To promote interest in training young skilled building workers, the Government has encouraged the development of suitable training schemes which have had a little success.

In printing, less attention is paid to the training of apprentices than in engineering or building. It is rare for a firm to have anyone specially responsible for the training of apprentices, and, as Lady Williams observes, it may be that there are some firms in the printing industry with well-organized works schools but they did not come to light in the inquiry. "For the most part the apprentice is put in the care of an adult craftsman and it is a matter of chance whether or not his teacher is an interested and capable teacher."

The motor-vehicle repairing industry is preponderantly composed of small units, is comparatively new, and has no tradition of apprenticeship or other regulated entry to the trade. It has an attractive scheme of training drawn up not only to attract additional workers to the industry but also because those concerned feel that they have a considerable responsibility for the safety of the general public. No mechanic is recognized as fully trained in the industry unless he has taken a part-time motor mechanic's course at a technical college, has passed the appropriate Intermediate City and Guilds examination and has successfully passed a practical examination set by the industry itself. The difference between this industry and others is that it has not been strangled by tradition.

After reviewing the present system of recruiting and training young workers for skilled jobs, Lady Williams turns to the future. In all essential points, she writes, the present system is exactly the same as the method introduced in the twelfth century; the old system of training has been carried on without any question of its suitability for a profoundly different situation.

Lady Williams is to be warmly commended for carrying out this first detached investigation into methods used by Britain's industry for training its young workers; their continuation along present lines could easily bring the nation to bankruptcy. As she disturbingly points out, it is astonishing that we still accept a system whereby apprenticeships must last five years, must begin at 16 and end at 21; in which each craft needs five years to master it; in which a boy who does not decide to become a craftsman at the age of 16 may, in general, never become one.

That the British method of producing skilled workers is not the only way is shown by experience in other countries. In the United States, for example, formal apprenticeship must last at least two years, but the period varies from one industry to another and may last five years. The age at which apprenticeship must begin is equally flexible. In many of the States there is no upper age limit for entry; in some it is 24 with allowances for higher age limits for ex-servicemen. Nor does an apprenticeship come to an end merely with the passage of time; in some trades an apprentice has to pass certain tests of competence before proceeding to further training or passing out as qualified.

What can be done by a determined nation has been shown by France. Before the Second World War the training of skilled workers was not in a very satisfactory state. The need for rebuilding a shattered economy exposed the extreme shortage of skilled workers; and as employers were afraid to commit themselves to a long period of training for young people, the technical section of the Ministry of Education undertook to provide a complete craft training in a full-time course lasting three years and covering a wide range of skills. The result has been to create a system of craft training which makes the British method one which the economy can no longer afford. The story is the same in Germany, Holland, Switzerland and other industrial countries.

Lady Williams's book should help to loosen some of the smugness and complacency which bedevils some sectors of British industry. It should be placed on the agenda for consideration of every board.

T. H. HAWKINS

FOUR-DIMENSIONAL GAS

The Relativistic Gas

By Prof. J. L. Synge. (Series in Physics.) Pp. xi+108. (Amsterdam: North-Holland Publishing Company, 1957.) 15 guilders.

THIS book is valuable, both in itself and as an addendum to the author's recent "Relativity: the Special Theory". That excellent treatise was remarkable for its combination of breadth and single-mindedness. All was based on four-dimensional space-time as a geometrical entity; and we were skilfully persuaded that flat four-dimensional geometry is as natural for non-gravitational theory as curved space-time is for general relativity. We may have qualms, however, when now we meet a direct four-dimensional approach to gas theory; for when the equations are automatically Lorentz-invariant one hesitates to enclose the gas in a three-dimensional bottle. A Lorentz transformation would send the bottle flying. Thus we should be happier if we fixed the bottle in our own space-frame, and merely examined the statistical effect of the relativistic variation of the masses of the gas particles with their individual velocities. F. Jüttner in 1911 and R. C. Tolman in 1914 had treated the equilibrium distribution from this point of view. Jüttner, coming closer to Synge, had transformed the distribution integral into a modified Bessel function, and also had noted incidentally the relevance of four-dimensional momentum-space to his transformation.

Prof. Synge begins directly with space-time and four-vector momentum. The 'points' of space-time are 'events', and the 'lines' the histories of free particles. Thus we have in a single picture the history of a gas of particles displayed as a 'broken discrete complex'—line fragments concurring in fours in collision-events. (It is suggested that this picture supports the notion that point-particles manage to collide because they are 'fated' to.) The gas is *not* bottled, and attention is concentrated first on the momentum distribution near some general point-event *A*. This is calculated by assuming that the 4-momentum has the most probable distribution for an assigned total flux over an elementary null-cone at *A*. The energy tensor then serves to identify the pressure of the gas (as a perfect fluid), and by its space-time conservation laws to give the equations of motion. Temperature is identified primarily as a common parameter in a gas mixture; but more thermodynamics appears in the last chapter, which treats the theory of shock-waves. This is of great interest, and the four-dimensional picture here is perspicuous. The mathematics of the shock velocity and temperatures involves the modified Bessel functions characteristic of relativistic distributions, rather awkwardly; but the author (assisted here by Mr. H. F. Sandham) completely overcomes the obstacles.

A basic tool in the earlier part is the "absolute 2-content of a 3-cell" on the pseudo-sphere of momentum of a particle. This 2-content is, rather strangely, proportional to the product of three differentials (being dimensionally the ratio of a 3-volume element to a length), but has the vital property of retaining significance when the rest-mass tends to zero and the pseudo-sphere to the null-cone. This concept enables the author to transfer the whole theory to zero-mass particles, which may be described as Maxwell–Boltzmann photons; the results are, as he says, too attractively simple to leave out. This characteristic lightness of touch serves as a foil to the solid achievement represented by the book, which provides a strong stimulus towards relativistic procedures and modes of thought.

N. B. SLATER

GUIDE TO ARCHÆOLOGY

Archæology and Society

Reconstructing the Prehistoric Past. By Prof. Grahame Clark. Third edition, revised. Pp. 272+24 plates. (London: Methuen and Co., Ltd., 1957.) 25*s*. net.

"ARCHÆOLOGY AND SOCIETY" was first published as long ago as 1939 and a second edition appeared in 1947. It is not surprising that ten years later a third edition has been called for. The first two-thirds of the volume are concerned with accounts of how discoveries can be made and what sort of direct evidence as to the life and outlook of our remote forerunners and ancestors can be deduced from them. This section has been entirely brought up to date and should be read and digested by every would-be prehistorian. The last third of the book attempts to probe deeper into the daily lives of prehistoric man. Unfortunately only certain materials can survive and only objects made of these materials can help us. Again, whether on the economic plane or on that of religion, some of the evidence that has survived can often be interpreted in many different ways. It is all too easy tacitly to assume that our modern outlook on things, or even that of modern primitive man, is the same as that of these prehistoric folk. It is all-important, therefore, that anyone who tries to tackle these problems should himself have the widest possible knowledge and, living as it were with them, should have almost come to see life through their eyes. No one could be found better qualified for this purpose than Dr. Grahame Clark, and his conclusions on these matters can, therefore, be accepted as very reasonable. The book is illustrated with line blocks and full page illustrations. It is very satisfactory that a third edition of this well-known work is now available.

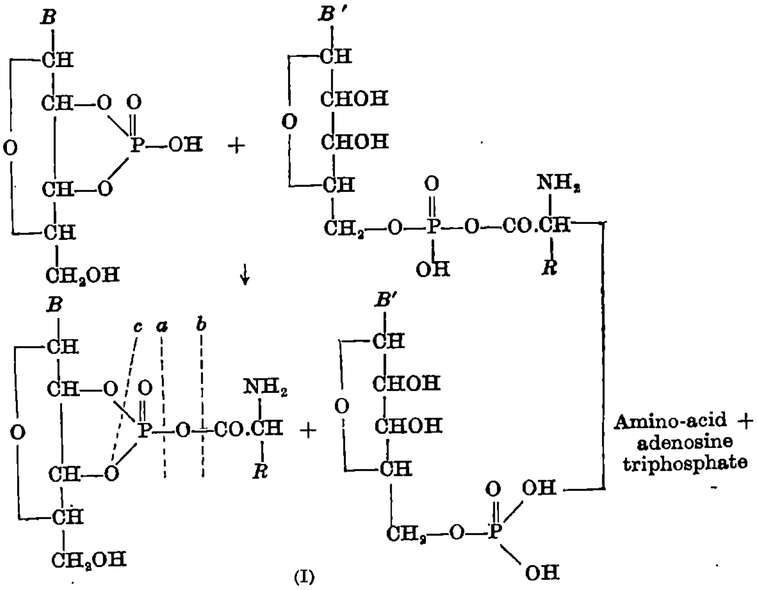
M. C. BURKITT

A HYPOTHESIS FOR THE BIOSYNTHESIS OF RIBONUCLEIC ACID AND PROTEIN

By Dr. A. M. MICHELSON

Arthur Guinness, Son and Co., Ltd., Chemist's Laboratory, St. James's Gate, Dublin

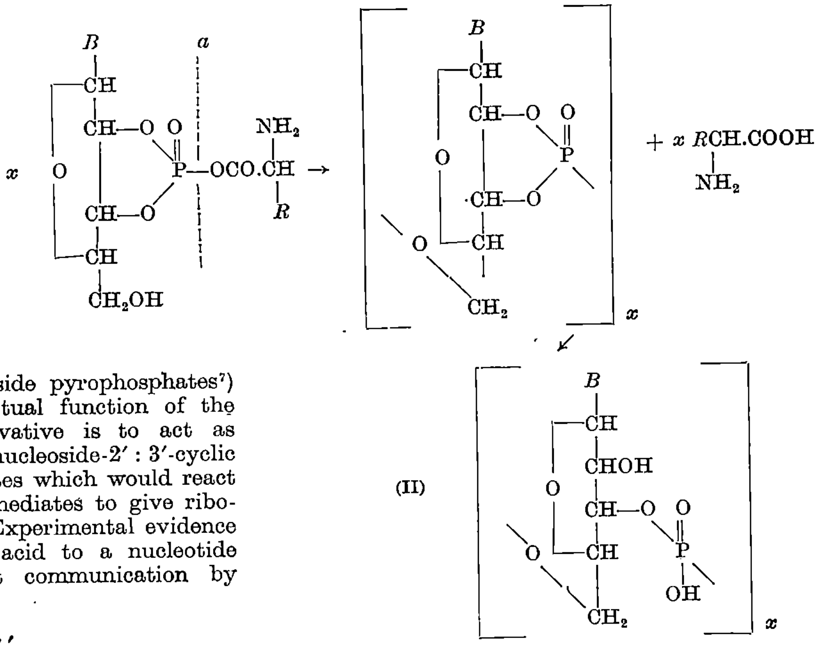
THE polymerization of nucleoside-2′ : 3′-cyclic phosphates by the action of acid anhydrides[1] is in some ways analogous to the enzymatic synthesis of di- and tri-nucleotides from pyrimidine cyclic phosphates by the action of ribonuclease[2] and may also have a bearing on the biosynthesis of both ribonucleic acid and protein. Amino-acid anhydrides of 5′-nucleotides have been described[3,4] and postulated as intermediates, as have non-identified precursors involving both an amino-acid and a nucleotide[5]. While it has been suggested[6] that polynucleotide formation occurs from the 5′-phosphate to a 3′-hydroxyl (as is the case in Ochoa's enzymatic polymerization of nucleoside pyrophosphates[7]) it is as feasible that the actual function of the 5′-nucleotide amino-acid derivative is to act as a specific anhydride on the nucleoside-2′ : 3′-cyclic phosphates to give intermediates which would react rapidly with other such intermediates to give ribonucleic acid and/or protein. Experimental evidence of such a transfer of amino-acid to a nucleotide factor is given in a recent communication by Webster[16].



(I)

Cleavage of this postulated intermediate could occur at each of the lines marked *a*, *b* and *c* (I). Fission at *a* or *b* is analogous to the acid or alkaline hydrolysis, respectively, of acetyl phosphate[8], while that at *c* is comparable with the hydrolysis at all *p*H's of dialkyl esters of uridine-3′-phosphate[9]. The consequences of such cleavage can be summarized as follows.

(1) Fission at *a* (acid catalysed). Attack at CH_2OH group. Synthesis of ribonucleic acid (reaction II).



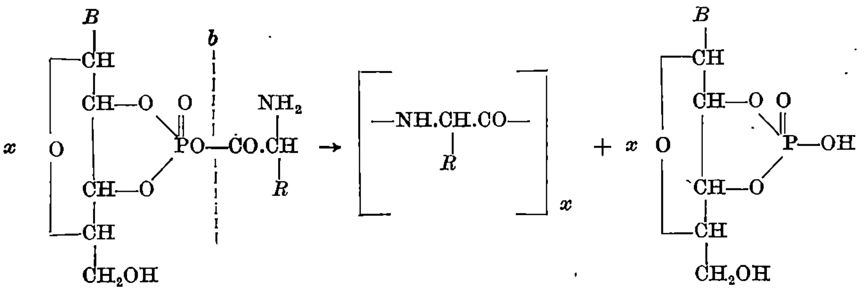
(II)

(2) Fission at *b* (base catalysed). Attack at NH_2-group. Synthesis of protein (reaction III).

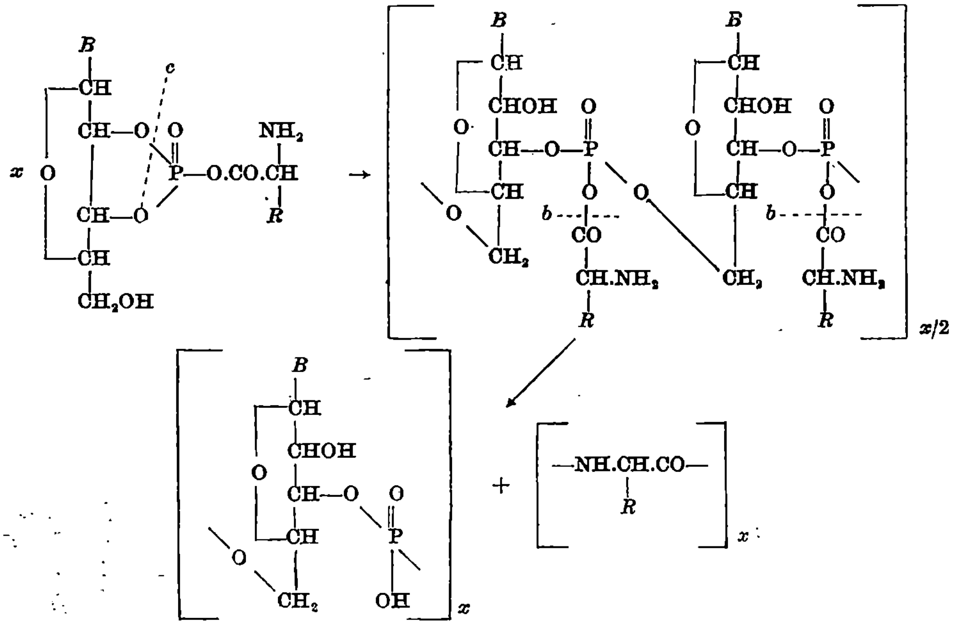
(3) Fission at *c*. Attack at CH_2OH group. Fission at *b*. Attack at NH_2-group. Synthesis of ribonucleic acid and protein (reaction IV).

Cleavage at *a* or *c* and attack at the amino-acid NH_2-groups would produce phosphoramidates, themselves reactive intermediates for mixed anhydrides[10,11], and can therefore be disregarded.

Earlier hypotheses[12,13] have postulated the transfer of amino-acid (activated through the carboxyl group) to a nucleic acid template to form an acyl anhydride with each internucleotide linkage, followed by formation of peptide bonds. With such hypotheses it is difficult to account for the inhibition of polynucleotide metabolism by inhibitors of protein synthesis which do not inhibit the incorporation of precursors into soluble nucleotides, that is, an effect concerned with the actual conversion of nucleotide into polynucleotide[14]; neither do they provide a ready explanation for the varying rates of protein and nucleic acid synthesis.

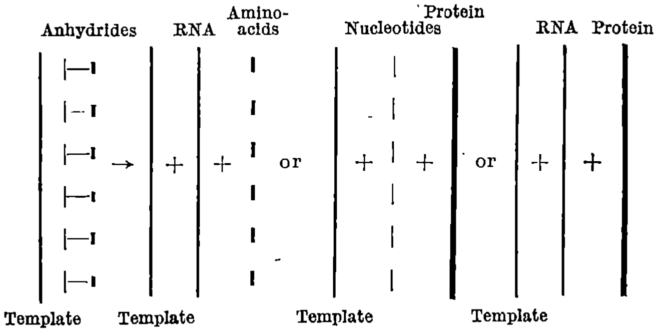


(III)



(IV)

It is suggested in the present hypothesis that biosynthesis occurs by the addition of nucleoside-2′ : 3′-cyclic phosphate–amino-acid anhydrides. The nucleotide bases are held by hydrogen bonding to a strand of nucleic acid in an order complementary to it, or to the enzyme itself. As each polymer (ribonucleic acid and/or protein) is formed the products peel away to assume their own characteristic configurations. Depending on the type of cleavage, directed enzymatically, possibly by control of effective local *p*H, either ribonucleic acid or protein or both ribonucleic acid and protein are formed. It is conceivable that small oligonucleotides would act as primers for such reactions, as with the polynucleotide phosphorylase of Ochoa[15].



The specificity of the process can be based not only on spatial considerations and bonding to a template, but also on the differences in acid strength of each component of the nucleoside cyclic phosphate–amino-acid anhydride and the basicity of each amino-acid, factors of possible significance under physiological conditions. In some degree each addition will be governed by the nature of both the terminal nucleotide–amino-acid and the succeeding nucleotide and its amino-acid. To some extent the template may only be necessary for limited 'active core' portions of the synthesized nucleic acid or protein, the other portions being restricted to a not too rigorously defined order and composition by purely chemical effects. While for cytoplasmic biosynthesis the template is the enzyme or ribonucleic acid, at some stage the information stored in the chromosomal deoxyribonucleic acid must be transferred to the cytoplasm. A tempting explanation is that the initial transfer is via such a mechanism as outlined above, a molecule of deoxyribonucleic acid or part of such a molecule being the template.

The essential part of this hypothesis accommodates most of the recorded biochemical data on the biosynthesis of peptides, proteins and nucleic acid[6,12] and is based on reasonable chemical analogies. It is hoped to develop such chemical aspects as the synthesis of oligonucleotide-peptides and ribonucleoprotein.

Thanks are due to the directors of Arthur Guinness, Son and Co. (Dublin), Ltd., for permission to publish this communication.

THE INFLUENZA VIRUS NEURAMINIDASE

By Dr. ALFRED GOTTSCHALK
The Walter and Eliza Hall Institute of Medical Research, Melbourne

University College of Science
PHYSICS Dept.
92, Upper Circular Rd, Calcutta

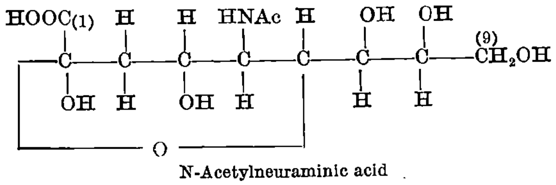
VIRUSES in their simplest form (tobacco mosaic virus, coliphages, polio virus) are nucleoproteins, the nucleic acid carrying the genetic information for the make-up of the virus generation to come, and the protein coat protecting the genetic material on its way from host cell to host cell. With increasing size the chemistry of the viruses becomes more complex. Irrespective of their composition, the viruses proper have no metabolism of their own. They integrate themselves into the metabolic pattern of their host cells. By imposing their code of sequence on the arrangement of the host building blocks in the enzymic synthesis of nucleic acids and proteins, they re-direct the chemical reactions to their own end[1]. The first serious challenge to the prevailing view that viruses are devoid of enzymes was the observation by Hirst[2] that chicken erythrocytes adsorbed influenza virus and by doing so were agglutinated. Whereas at 4° C. the virus remained attached to the red cells for 18 hr. or more, at 37° C. spontaneous elution of the virus from the cells soon occurred. The virus liberated was intact, leaving behind, however, the red cells inagglutinable by fresh virus. Hirst's interpretation, logical and ingenious, was that a receptor substance present at the surface of the red cell attracted and bound the virus, which in turn by virtue of an enzyme embedded in its coat acted upon the receptor. The viral enzyme-receptor interaction was envisaged as resulting in a chemical change of the receptor substance concomitant with the release of the unimpaired virus particle. The same sequence of events—adsorption and spontaneous elution of the virus—was demonstrated[2] with the system influenza virus and surviving host cells deprived of their normal blood supply (respiratory cells of the excised ferret lung).

Much weight was added to Hirst's interpretation by subsequent discoveries made by Burnet and his co-workers[3]. They showed that a variety of materials secreted by mucus membranes such as gastric and intestinal mucin, bronchial mucus, ovarian cyst fluid, cervical mucus, etc., strongly inhibited hæmagglutination by indicator virus, that is, virus treated (by heat) in such a way as to prevent it being eluted spontaneously from erythrocytes. When digested with active virus, these inhibitory mucins lost their biological activity. Most useful and important was the preparation by Burnet *et al.*[3] from the culture filtrate of *Vibrio cholerae* of an enzyme imitating the effect of the influenza virus on the cellular receptors and the inhibitory mucoproteins. Pretreatment with the vibrio enzyme rendered the erythrocytes inagglutinable, the mucoproteins non-inhibitory and the intact host cells non-susceptible to virus infection.

The biochemical approach to the problem of the viral enzyme was initiated by the finding[4] that living influenza virus, when acting upon hæmagglutinin inhibitory mucoproteins and reducing their inhibitory capacity by 99 per cent, released from them a compound of low molecular weight separable by dialysis from the digest. On purification this compound (split product) was shown to have reducing power, to contain nitrogen and to form in the Morgan–Elson reaction a purple-coloured substance indistinguishable spectrophotometrically from that given by N-acetyl D-glucosamine under similar conditions[4]. However, in contrast to amino-sugars, the split product gave a direct Ehrlich reaction and a positive Bial's orcinol test, and it decomposed with formation of humin on treatment with mild acid[4,5]. The split product was the same whether a mucoprotein fraction of hen egg-white (ovomucin) or an electrophoretically homogeneous mucoprotein from human urine was taken as substrate, whether influenza virus or vibrio enzyme was used as catalytic agent. Appropriate controls with heat-inactivated virus were negative[4]. These results left no doubt about the enzymic nature of the process. Moreover, it was established that the enzyme is an intrinsic compound of the virus particle itself and that a similar enzyme is not present in the host cells of the virus[1].

A compound with the same properties as those described for the split product was first isolated from bovine submaxillary gland mucoprotein by Blix[6]. This compound, termed by Blix *et al.*[7] sialic acid, was eventually proved to have the composition $C_{13}H_{21}O_{10}N$ and to contain an N-acetyl group, an O-acetyl group which is easily split off, a carboxyl group, an α-keto or α-hydroxyl group, a primary alcohol group and a group titratable by hypoiodite[7]. Klenk and Lauenstein[8], treating bovine submaxillary gland mucoprotein and human urine with 5 per cent methanolic hydrochloric acid, obtained methoxyneuraminic acid, a substance resembling sialic acid in the reactions carried out at acid *p*H, but differing from it in being non-reducing, alkali-stable, ninhydrin-positive, free of acetyl and in possessing a methoxy group. The close relationship between sialic acid and neuraminic acid became obvious when N-acetylneuraminic acid was isolated from the hydrolysate of bovine submaxillary gland mucoprotein[9]. Confirming the earlier observations on the release of the split product from human urine by virus action, Klenk *et al.*[9] crystallized the product and identified it as N-acetylneuraminic acid. It seemed that the latter differed from sialic acid only in the lack of an O-acetyl group. Therefore, N-acetylneuraminic acid and methoxyneuraminic acid would be expected to have the composition $C_{11}H_{19}O_9N$ and $C_{10}H_{19}O_8N$, respectively. Instead, Klenk *et al.*[8,9] assigned to them the formulæ $C_{12}H_{21}O_{10}N$ and $C_{11}H_{21}O_9N$.

The molecular structure of N-acetylneuraminic acid, exhibiting properties of both an amino-sugar and a 2-deoxyhexose, remained obscure until a well-defined degradation product was prepared. Bovine submaxillary gland mucoprotein and human urine, on treatment with alkali, yielded pyrrole-2-carboxylic acid, and the same pyrrole derivative was obtained from the split product[10]. On this basis and on the other information available, neuraminic acid was envisaged as an aldol-condensation product of D-glucosamine (or D-galactosamine) with pyruvic acid, methoxyneuraminic acid as the methylglycoside of neuraminic acid, N-acetylneuraminic acid as the N-acetylated neuraminic acid and sialic acid as ON-diacetylneuraminic acid[10]. This concept was strengthened by the synthesis[10] of pyrrole-2-carboxylic acid from D-glucosamine and pyruvate at pH 11·0 and was confirmed by the reverse aldolization of N-acetylneuraminic acid to N-acetylglucosamine and pyruvic acid[11] or pyruvic acid degradation products[12]. Its final proof was derived from the synthesis of N-acetylneuraminic acid from N-acetyl D-glucosamine and carboxylated pyruvic acid (oxaloacetic acid), the synthetic compound being chemically and stereochemically identical with the crystalline compound of biological origin[13]. By the method of synthesis the carbon skeleton, the nature and position of the functional groups are determined and Blix's formula proved to be correct. The stereochemistry at C_2 and C_4 of crystalline N-acetylneuraminic acid was recently elucidated[14]. The pyranose structure and the position at C_7 of the O-acetyl in diacetylneuraminic acid follow from the results of periodate oxidation[7].



N-Acetylneuraminic acid

It was early recognized that the inhibitory mucoproteins are conjugated proteins containing as prosthetic groups polysaccharides or oligosaccharides of small size distributed in numbers along the polypeptide chain[1]. Sialic acid, in the new terminology[15] the group name for all acylated neuraminic acids, occupies a terminal position in the prosthetic groups and is linked through its potential keto-group glycosidically to the adjacent sugar unit[10]. Bovine submaxillary gland mucoprotein contains about 17 per cent diacetylneuraminic acid and an equimolar amount of N-acetylgalactosamine besides very small quantities of N-acetylglucosamine, galactose, mannose and fucose. At pH 1·0 and 80° C., 78 per cent sialic acid—and sialic acid only—is released; vibrio enzyme splits off 64 per cent of the sialic acid present in bovine submaxillary gland mucoprotein. The prosthetic group may be detached by very dilute alkali. It has been obtained as a white substance in an analytically pure state; its formula is $C_{19}H_{32}O_{14}N_2$ and it consists of N-acetylneuraminic acid linked ketosidically to N-acetylgalactosamine. The viral enzyme and vibrio enzyme split the disaccharide into N-acetylneuraminic acid and N-acetylgalactosamine (Gottschalk, A., and Graham, B., in preparation). The ready conversion even at room temperature of the disaccharide at pH 10 and at pH 2 to chromogen-disaccharides, that is, disaccharides the N-acetylgalactosamine moiety of which is transformed to a chromogen in the direct Ehrlich reaction, would suggest linkage of N-acetylneuraminic acid to C_5 of the amino-sugar (in its furanose form), though linkage to C_6 cannot be excluded. A furanose structure of N-acetylgalactosamine within the disaccharide would also account for the direct Ehrlich reaction of the latter in the cold and for the ease with which N-acetylneuraminic acid is released from bovine submaxillary gland mucoprotein at its own pH. These new findings may necessitate re-interpretation of previous observations on the prosthetic group[16].

The specificity of the virus enzyme and vibrio enzyme is not absolute. Thus the above disaccharide, three chromogen-disaccharides and sialyl-lactose, a reducing trisaccharide consisting of diacetylneuraminic acid, linked α-ketosidically to lactose[14], are readily hydrolysed by the enzyme. N-glycolyneuraminic acid, the sialic acid of porcine submaxillary gland mucoprotein, is split off from this mucoid by vibrio enzyme[9]. The influenza virus enzyme and the isodynamic vibrio enzyme may, therefore, be defined as neuraminidases cleaving the α-ketosidic linkage joining the terminal acylated neuraminic acid to another sugar or sugar derivative.

Finally, it may be mentioned that N-acetylneuraminic acid has been obtained crystalline from human erythrocytes by the action of vibrio neuraminidase[9]. This achievement suggests that the cellular receptors are sialylmucoproteins like their chemical analogues, the hæmagglutinin inhibitory mucoids. The sialic acid component of both the cellular and the soluble receptors is instrumental in attracting and binding the virus, and the release of sialic acid from both types of receptors by the action of neuraminidase results in the loss of their biological activity.
